HISTORY

The problem with writing about history is that developments appear inevitable and indeed when we present a chronological account this must be the case. However, it is as well to remember that at each point in the story the outcome could have been different. The advances in medicine in the twentieth and twenty-first centuries are the result of the demonstration of the validity of the germ theory in the nineteenth century and most significantly the establishment of its functional utility. It is easy to forget how recent these advances are. In 1922, Topley succeeded Sheridan Delépine in the Bacteriology Department of the University of Manchester. Delépine had worked with Pasteur. This was a world before molecular biology, before most immunology, and at the beginnings of antimicrobial chemotherapy. Here, some of the advances are documented, but the choice of what to include is determined by the concerns of the present and the recent past and may not reflect fully the concerns and priorities of the past.

MICROBIOLOGY

Microbiology is the study of living organisms ('microorganisms' or 'microbes'), simple in structure, and usually small in size, that are generally considered to be neither plants nor animals; they include bacteria, algae, fungi, protozoa, and viruses. 'Pure' microbiology concerns the organisms themselves and 'applied' microbiology their effects on other living beings, when they act as pathogens or commensals, or on their inanimate environment, when they bring about chemical changes in it. Thus, microbiology has applications in human and veterinary medicine, in agriculture and animal husbandry, and in industrial technology and even climatology.

Microorganisms were first seen and described by the Dutch lens-maker Antonie van Leeuwenhoek (1632–1723), who devised simple microscopes capable of giving magnifications of c. $\times 200$. In a number of letters to the Royal Society of London between 1673 and his death, he gave clear and accurate descriptions and drawings of a variety of living things that undoubtedly included protozoa, yeasts, and bacteria (Dobell 1932). These striking observations did not lead immediately to great advances in the knowledge of microbes. These were delayed for nearly two centuries, until essential technical advances had been made by workers who nowadays would be described as industrial or medical microbiologists.

When bacteriology started in the nineteenth century the borders of the discipline were uncharted and much of what would now be called virology and immunology was included. More recently bacteriology has contributed to, or perhaps been subsumed by, the emergence of molecular biology. Such categories are largely arbitrary and the concern here is to present an outline that does justice to the roots of the subject.

COMMUNICABLE DISEASES

Long before microbes had been seen, observations on communicable diseases had given rise to the concept of contagion: the spread of disease by contact, direct or indirect. This idea was implicit in the laws enacted in early biblical times to prevent the spread of leprosy. It became less influential in the classical era, when supernatural and miasmatic causes were favored. In the later Middle Ages, there was renewed interest in contagion, reinforced at the end of the fifteenth century by the spread of syphilis in Europe, which was obviously associated with a specific form of contact. Fracastorius (Girolamo Fracastoro), a physician of Verona, published an influential analysis of contagion in 1546:

- by physical contact alone
- by formites, and
- at a distance.

He was led to conclude that communicable diseases were caused by living agents; these he spoke of as 'seminaria' or 'seeds,' but he was unable to give a more definite opinion about their nature.

In the subsequent 250 years, several authors speculated that the agents of contagious diseases were animate, but little evidence for this was produced. Even the recognition of parasitism of animals, e.g. scabies and some forms of helminthiasis (see Foster 1965), appears to have had little impact on thinking about the role of microorganisms as pathogens. Early in the nineteenth century, improvements had been made in the design of microscopes and between 1834 and 1850 numerous accounts were published of morphologically recognizable microorganisms in material from diseased animals or human subjects: of fungi subsequently called *Botrytis* in the silkworm disease 'calcino' by Bassi; of trichomonads in human vaginal discharges by Donné; of ringworm fungi by Schönlein and by Groby; of vibrios in cholera stools by Pouchet; and of large rod-shaped bacteria in anthrax blood by Rayer and Davaine (for references see Bulloch 1938).

THE 'GERM THEORY'

In 1840, Henle affirmed his belief in what came to be called the 'germ theory of disease,' which asserted that certain diseases were caused by the multiplication of microorganisms in the body, but he advanced little supporting evidence for this and his view was hotly disputed.

The lack of a germ theory probably led to the initial rejection by the General Board of Health in 1854 of Snow's explanation of the waterborne spread of cholera in London. In groundbreaking investigations, Snow established that cholera was spread by water contaminated with human feces; however, these findings conflicted with the miasmatic theory and their significance was not fully realized until the germ theory was accepted. As late as 1894 Creighton, in his still unsurpassed 'History of Epidemics in Britain,' based his understanding on the miasmatic theory.

The intellectual and scientific case for the germ theory was established by the studies of Koch and Pasteur, which are set out below, but there was no immediate widespread acceptance. The Hamburg cholera outbreak and the dispute between Koch and Pettenkoffer both publicized and showed the strength of the theory. Drinking water from Hamburg was taken from the river Elbe above the town and sewage was discharged into the river. In Hamburg there were many cases of cholera. Altona, downstream from Hamburg, also drew drinking water form the Elbe; however, this water passed through slow sand filters before distribution. In Altona there were only a few cases of cholera. The demonstration that removal of contamination from the water supplies prevented infection convinced the public and the medical profession of the bacterial etiology of the disease. In spite of this elegant demonstration of the waterborne transmission of *Vibrio cholerae* and the mechanism for control, not all were convinced. Pettenkoffer and Emmerich both drank 1 ml of *V. cholerae* culture. Both survived (Pettenkoffer 1892). This publicity undoubtedly helped to popularize the theory.

FERMENTATION AND PUTREFACTION

In the first half of the nineteenth century, chemists became interested in fermentation: industrial processes in which organic substances underwent changes that yielded useful compounds, such as alcohol and acetic acid. A similar process, termed putrefaction, led to the decay of organic matter, usually with the production of an unpleasant odor and taste. In the 1830s, several observers, notably Cagniard-Latour and Schwann, saw yeasts in liquors undergoing alcoholic fermentation and concluded that these were living organisms and the cause of the process. This view was resisted by leading authorities of the day (Berzelius, Liebig, Wohler), who considered that fermentation was a purely chemical process and that the yeasts were a consequence rather than the cause of it. Between 1836 and 1860 controversy raged but without a clear outcome.

The work of Louis Pasteur

Louis Pasteur (1822–1895) (Figure 1) produced strong experimental evidence that microorganisms were the cause of fermentation and in so doing laid the foundations of microbiology as a science. He was a chemist whose early studies of fermentation aroused his interest in the molecular asymmetry of some of the compounds formed. He concluded that optically active chemical compounds, such as the stereoisomeric forms of tartaric

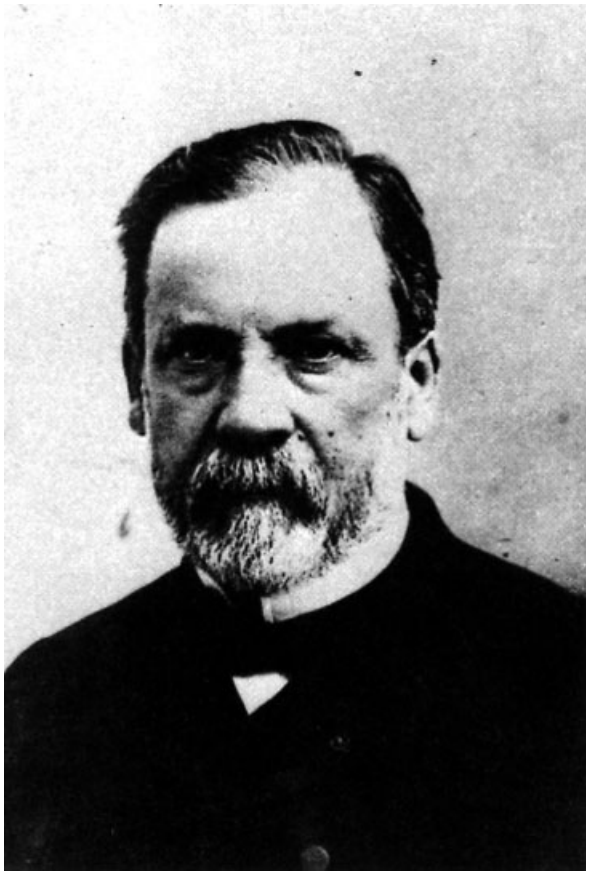

Figure 1 *Louis Pasteur (1822–1895).*

acid and amyl alcohol, never arose from the purely chemical decomposition of sugars but were formed from them by the action of microorganisms; these were always present in fermenting liquors and increased in number as the process continued. Different fermentation processes (e.g. alcoholic, acetic, butyric) were each associated with particular organisms, which were often recognizable by their morphology or requirements for growth.

To maintain that microorganisms caused fermentation, it was necessary to establish that they did not arise de novo. This was contrary to the widely held belief in the spontaneous generation of living things from dead animal or vegetable material ('heterogenesis'). Controversy about this in the eighteenth century had centered around the conditions under which putrefaction developed in organic matter that had been subjected to supposedly sterilizing temperatures in closed containers. This matter was unresolved in 1860. In a series of admirable experiments reported in the next 4 years (see Vallery-Radot 1922–33), Pasteur disposed of many purported instances of heterogenesis by showing that they could be attributed to failure of the initial sterilization or to subsequent recontamination. He emphasized the need for scrupulous sterilization of everything coming into contact with the material under examination and demonstrated numerous sources of contamination from air, dust, and water. He showed that some organisms were not destroyed by boiling. For the sterilization of fluids, he advocated heating to 120°C under pressure, and for glassware, the use of dry heat at 170°C; he showed the value of the cottonwool plug for protecting material from aerial recontamination.

In the course of these experiments Pasteur used various forms of nutrient fluid to grow microorganisms and showed that a medium suitable for one might be unsuitable for another, so for successful cultivation it was necessary to discover a suitable growth medium and to establish optimal conditions of temperature, acidity or alkalinity, and oxygen tension.

The mass of experimental data produced by Pasteur carried general conviction, but a minority of adherents of heterogenesis continued to maintain their position, often supporting this by experiments in which inadequate heating had failed to destroy very heat resistant bacteria. The observations of Tyndall in the early 1870s, that all actively multiplying bacteria were easily destroyed by boiling, led to the introduction of a method of sterilization by repeated cycles of heating interspersed with periods of incubation. This method of 'tyndallization' served to eliminate many of the anomalies reported by the advocates of heterogenesis (see Bulloch 1938).

Pasteur devoted much effort to investigating the troubles of French winemakers, brewers, and vinegar makers. These studies often led him to perform experiments of fundamental scientific importance, as when his involvement in the problems of vinegar making led to valuable observations on the constancy of microbial characters in culture. His general conclusion was that fermentations owed their diversity to the characters of the several organisms responsible for them, but final proof of this was not obtainable until methods of obtaining pure cultures had been discovered.

PATHOGENIC MICROORGANISMS

In about 1865, Pasteur responded to an appeal to investigate a formidable disease of silkworms in southern France (pébrine); by 1869, his experiments had led him to the conclusion that this was a communicable disease transmitted by direct contact or fecal contamination. This, according to his biographer Vallery-Radot (1919), engendered in his mind the idea that communicable diseases of animals and man, like the 'diseases' of wine and beer, might be a consequence of microbial multiplication.

From 1857 onward there had been reports, notably by Brauell and Davaine, of the transmission of anthrax between animals by the injection of blood. At that time there was also much interest in the septic and pyemic diseases of man, including 'surgical fever' (see Bulloch 1938). In 1865, Coze and Felty began to publish a series of papers reporting the presence of bacteria in the blood

of dogs and rabbits that had received injections of purulent material from human patients. In 1872, Davaine, starting with blood from patients suffering from 'putrid' infections, performed serial passage in experimental animals and demonstrated enhancement of virulence.

Joseph Lister (1827–1912) was aware of Pasteur's demonstration that both fermentation and putrefaction might be initiated by airborne organisms. On the assumption that 'putrefying' wounds might be similarly caused, he attempted to prevent surgical sepsis by denying access to wounds of microbes from the patient's surroundings, particularly from the air. His 'antiseptic' regimen, first described in 1867, was strikingly successful and transformed the prognosis of major surgical operations. Lister did not prove that this was due to the destruction of potentially pathogenic microbes, but this was rendered highly probable by the contemporary work of French and German bacteriologists.

In retrospect, the work of another surgeon, Alexander Ogston (1844–1929), who described staphylococci in pus, assumes perhaps equal importance and helped lay the foundations for the study of hospital infection. The history of hospital infection was reviewed by Selwyn (1991) and Ayliffe and English (2003).

The work of Robert Koch

In 1876, while a country physician at Wollstein in eastern Germany, Robert Koch (1843–1910) (Figure 2) published his first scientific work, a study of the anthrax bacillus in experimental animals, of its growth in vitro, and of the formation and germination of its spores. This opened up a new era in bacteriology. In the following year, he described the fixing and staining of bacteria with the newly introduced aniline dyes. In 1878, his study of wound infections explored the role of animal experimentation in establishing the cause of bacterial infections. Then, in 1881, he described means of cultivating bacteria on solid media, thus making it possible to obtain pure cultures by transferring material from a single colony. First he used pieces of potato as his growth medium, then nutrient gelatin, and later agar gel media. In 1882 and 1884, he published classic papers on the tubercle bacillus, and in 1883, he described the cholera vibrio.

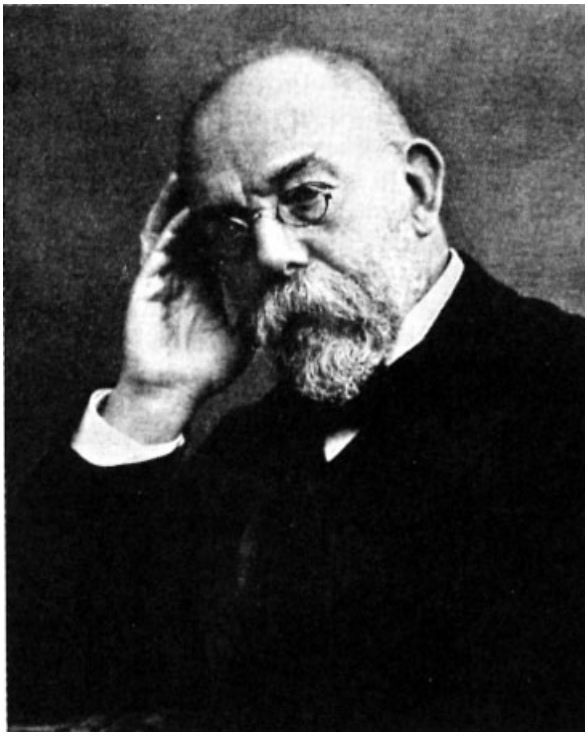

Figure 2 *Robert Koch (1843–1910).*

Koch had now assembled the techniques needed to investigate the bacterial causes of many communicable diseases. He had moved to Berlin, where Loeffler and Gaffky were already his assistants; later came Pfeiffer, Kitasato, Welch, and many others. Koch began to gather round him the group of followers who were destined to introduce his methods into many laboratories throughout the world.

We should remember that not all the techniques were devised by Koch; agar was first used by Hesse at the suggestion of his wife Fannie. In 1887, Petri described his culture dish, which remains a mainstay of bacteriological isolation.

The fruits of this technical revolution appeared with remarkable speed during the years 1876–90, the period described by Bulloch (1938) as 'the heyday of bacterial etiological discovery,' when most of the important groups of bacterial pathogens for man and animals were recognized.

Differential staining

In 1878, Paul Ehrlich had noted differences in the affinity for aniline dyes of various types of living cells, an observation that started him on his long search for chemotherapeutic agents. In 1882, he reported that tubercle bacilli stained with fuchsin retained the dye when subsequently treated with a mineral acid; this property of 'acid-fastness' formed the basis for methods later developed to detect mycobacteria in tissue sections, in sputum and other secretions, and in cultures.

A differential staining method of even wider applicability arose from the observation, reported in 1884 by the young Danish physician Christian Gram, that certain bacteria, when stained with methyl violet and treated with an iodine solution as a mordant, retained the violet dye when washed briefly with ethyl alcohol. The 'gram reaction' proved to be a useful means of dividing bacteria into two categories: 'gram-positive' organisms that were stained violet and 'gram-negative' organisms that lost the violet dye and were stained red by a

counterstain applied after washing with alcohol. This property was later found to reflect differences in cell-wall composition and to be correlated with a number of other characters; organisms that retained the violet stain were in general less susceptible, than those that did not, to various chemical substances and to lysis by complement in the presence of specific antibody.

Establishing the pathogenicity of bacteria

As the number of different bacteria found in constant association with human and animal diseases grew, the question of how to establish their etiological role assumed importance. Already in the 1880s it was being recognized that, though the internal organs were normally sterile or nearly so, many surface sites and body cavities communicating with the outside had a rich bacterial flora, so the presence of an organism here was of little significance. When inflammatory lesions appeared in such places it was often difficult to decide which, if any, of the organisms present was responsible.

Koch's experience with anthrax, wound infection, and tuberculosis led him to place much reliance on the evidence of animal experimentation in establishing relationships between disease and isolate. A set of conditions, all of which must be fulfilled to justify such a conclusion, has been called Koch's postulates. They are as follows (see Topley and Wilson 1931), though Koch did not state them in precisely this form:

- the organism is regularly found in the lesions of the disease
- it can be grown in pure culture outside the body of the host for several generations, and
- such a culture will reproduce the disease in question when administered to a susceptible experimental animal.

It subsequently proved difficult or impossible to fulfill all these criteria in respect of many microbial diseases.

Immunity

Folk medicine had long established that exposure to certain infective agents might engender immunity to them (Parker 1998) and experience with Jennerian vaccination against smallpox had indicated the value of selecting a strain of the agent with low virulence for use as an inducer of immunity. While Koch and his pupils were continuing to characterize more and more pathogens, Pasteur turned his attention to the possibility of inducing prophylactic immunity by injections of live cultures of organisms, the virulence of which had been attenuated by prolonged culture or by growth under suboptimal conditions. Success was reported in 1877 with a live vaccine against the pasteurella of chicken cholera and in 1881 with one against anthrax in animals. In 1886, Pasteur reported on the use of an attenuated live vaccine against rabies. This consisted of a dried suspension of spinal cord from an infected rabbit. Its use was an extension of the original principle of vaccination in that the material was given after infection had taken place. It was used with apparent success to prevent disease in human subjects who had been bitten by a rabid animal. Most of the early attenuated living vaccines caused appreciable morbidity and even some deaths, but in 1886, Salmon and Smith showed that it was possible to protect pigeons against salmonella infection by the injection of heat-killed organisms. Pfeiffer demonstrated in 1889 that immunity conferred by vaccination was usually highly specific, but there were exceptions to this.

At a somewhat earlier date, Metchnikoff had observed the engulfment of bacteria and other microbes by phagocytes; in 1891, he expressed the view that immunity was primarily cellular. This conflicted with growing evidence for the importance of serum factors; the alternative humoral view of immunity was that 'antibodies' appeared in the serum of vaccinated or infected animals and that their specificity corresponded to that of the 'antigens' that elicited them.

Strong evidence for humoral immunity emerged after Roux and Yersin in Paris had demonstrated in 1888 the characteristic lethal effects of broth cultures of diphtheria bacilli on guinea-pigs and shown that these were caused by the liberation of a soluble toxin, an 'exotoxin.' In the following year, Behring in Koch's laboratory observed that chemically sterilized broth cultures of diphtheria bacilli retained their toxicity for guinea-pigs but animals given sublethal doses of them were subsequently immune to diphtheria. He also showed that the pleural fluid of animals dead of diphtheria was toxic but yielded no diphtheria bacilli on culture; however, injections of it rendered other guinea-pigs immune. By 1890, Behring had demonstrated that the blood of immunized guinea-pigs neutralized diphtheria toxin in vitro. Faber demonstrated tetanus toxin in 1889; the following year, Behring and Kitasato immunized rabbits against it and showed that their serum protected mice against tetanus.

By 1890, many of the basic areas of immunology had been outlined, though some concepts that are now considered as basic were discovered surprisingly late. The secondary response was described by Glenny and Sudmerson (1921) and the concept of herd immunity by Topley and Wilson (1923). These events set the study of immunity on a firm foundation and form the basis of the discipline of immunology; the further history can be found in the Immunology volume History.

The chronology of these events is summarized in Tables 1 and 2. Figure 3 shows the Bacteriological

Table 1 *Bacteriology in the nineteenth century*

Year	Event
1834–50	Fungi, protozoa, and bacteria seen in diseased tissues or secretions (see text)
1836–37	Yeasts seen in liquors undergoing alcoholic fermentation
1840	Henle: 'germ theory of disease'
1844–57	Pasteur: studies optically active compounds from fermented fluids
1849-54	Snow: waterborne transmission of cholera
1857–63	Pasteur: reports that anthrax is transmitted by injections of blood from diseased animals
1860–64	Pasteur: experimental evidence that fermentation and putrefaction are effects of microbial growth
1865–67	Pasteur studies 'pébrine' of silkworms; concludes that it is caused by microbial action
1867	Lister: success of 'antiseptic surgery' supports view that microbes cause postoperative sepsis
1876	Koch: demonstrates pathogenicity and sporulation of anthrax bacilli
1877	Koch: staining of bacteria by aniline dyes
1877	Tyndall: heat-resistant bacteria destroyed by repeated cycles of moderate heating and incubation
1877	Pasteur: chicken cholera prevented by injections of live attenuated culture
1877	Soil nitrates replenished by microbial action
1878	Koch: studies of wound infection; use of experiments on animals to establish etiology
1879	Ehrlich: differences in affinity of chemical substances for various sorts of living cells
1880	Ogsten: staphylococci in pus
1881	Koch: use of solid media to obtain pure cultures of bacteria
1881	Pasteur: anthrax prevented by live attenuated vaccine
1882	Ehrlich: acid fastness of the tubercle bacillus
1882	Hesse: use of agar to solidify culture media
1882–84	Koch: etiological role of the tubercle bacillus; 'Koch's postulates'
1883	Koch describes the cholera vibrio
1883–91	Metchnikoff studies cellular defence mechanisms
1884	Chamberland filters
1884	Gram's stain
1886	Pasteur's rabies vaccine
1886	Salmon and Smith: killed bacterial vaccines effective
1887	Petri: double-sided culture dish
1888	Roux and Yersin: diphtheria bacillus forms exotoxin
1888	Nuttall: serum killing of bacteria
1889	Behring: antitoxic immunity to diphtheria
1889	Pfeiffer: specificity of immunity conferred by vaccines
1889	Faber: tetanus bacillus forms exotoxin
1889	Buchner: serum killing of bacteria inhibited by heating the serum
1890	Behring: diphtheria antitoxin neutralizes toxin in vitro
1890	Behring and Kitasato: antitoxic immunity to tetanus
1890	Winogradsky: nitrite- and nitrate-forming bacteria in soil
1892	Tobacco-mosaic disease transmitted by filtered material
1894	Pfeiffer's phenomenon: lysis of vibrios in peritoneal cavity
1895	Bordet: heat-stable and heat-labile factors (respectively, antibody and complement) in immune lysis
1897	Ehrlich: 'side-chain theory' of antibody production
1898	Foot-and-mouth disease transmitted by filtered material

Section of the Congress of Hygiene and Demography, London, 1891.

Bacterial filters and the origins of virology

An important technical advance in the latter part of the nineteenth century was the development of filters that held back bacteria but allowed the passage of smaller microorganisms and biologically important macromolecules: in 1884, Chamberland introduced filters made of unglazed porcelain and in 1891 Nordtmeyer introduced the Berkefeld-type of filter composed of kieselguhr. There were several important consequences of these innovations, as follows.

Filtration provided a convenient means of producing bacteria-free preparations of soluble toxins and thus greatly simplified the task of producing reagents for passive and active immunization against diphtheria and tetanus. It was also an essential preliminary to the

Table 2 *The twentieth century*

Year	Event
1900	Reed: yellow fever virus
1911	Rous: chicken sarcoma caused by a virus
1912	Ehrlich and Hata: Salvarsan for the treatment of syphilis
1915/17	Twort and d'Herrelle: 'bacteriophage'
1921	Glenny and Sudmerson: the secondary response to antigen
1923	Topley and Wilson: herd immunity
1928	Griffith: the transformation of pneumococci
1929	Fleming: penicillin – the first antibiotic
1935	Domagk: prontosil – the first suphonamide
1944	Avery, MacLeod, and McCarty: DNA as the agent of transformation
1944	Schartz, Bugie, and Waksman: streptomycin – the first antituberculosis treatment
1946	Lederberg and Tatum: conjugation in bacteria
1952	Lederberg and Zinder: phage transduction of bacteria
1953	Crick, Franklin, Watson, and Wilkins: structure of DNA
1960	Jacob, Perrin, Sanchez, and Monod: the operon concept
1961	Brenner, Jacob, and Meselson: ribosomes site of protein synthesis
1973	Cohen, Chan, Helling, and Boyer: plasmid vectors
1977	Fox, Pecham, and Woese: molecular systematics (16S RNA)
1977	Woese: Archaebacteria
1977	Gilbert and Sanger: DNA sequencing
1986	Mullis: the polymerase chain reaction (PCR)
1995	Venter, Smith, and Fraser: genome sequence of *Haemophilus influenzae*

purification of toxins and to chemical studies of their constitution.

It soon became apparent that some disease agents passed through bacteria-retaining filters; thus, the first viral pathogens were recognized. In 1892, Iwanowski described the transmission of mosaic disease to tobacco plants and, in 1898, Loeffler and Frosch described the transmission of foot-and-mouth disease in bovines by the injection of filtrates of infective material. In 1900, Walter Reed demonstrated that yellow fever is caused by a filterable agent (Reed 1902). The further history of virology is dealt with in the Virology volume,
A short history of research on viruses.

A later consequence of the use of bacterial filters was the discovery, independently by Twort in 1915 and by d'Herelle in 1917, of bacteriophages, subsequently shown to be viruses that multiply in bacterial cells. Intensive study of the interaction of bacteriophage and bacterium by Delbrück and Hershey in the early 1940s contributed much to the knowledge of viral infections and also led to important developments in bacterial genetics (see Bacterial genetics).

NONMEDICAL APPLICATIONS OF BACTERIOLOGY

The discoveries of Pasteur and Koch had important applications for agriculture and industry. The replacement of nitrates lost from the soil by the washing action of rain had long been a mystery but it seemed to be connected in some way with the decomposition of organic matter. In 1877, Schloesing and Muntz, acting on a suggestion from Pasteur, showed by experiment that the formation of nitrates was due to the action of living organisms. Warington confirmed this in 1878 and 1879 and demonstrated that the process took place in two stages: first, the conversion of ammonia to nitrites, and then the oxidation of nitrites to nitrates. He believed that these two stages were performed by different organisms but failed to prove this. In 1890, Winogradsky isolated and described the nitrogen-fixing bacteria that caused the formation of nodules on the roots of leguminous plants. Later, Winogradsky described a free-living anaerobic organism that fixed atmospheric nitrogen and Beijerinck, some 10 years afterwards, described a large free-living nitrogen-fixing aerobe that he named *Azotobacter*.

The importance of bacteria in maintaining the fertility of the soil has thus been recognized for over a century. A more recent concept is that the chemical activities of primitive ancestral microbial forms may have created the atmospheric conditions essential for the appearance of plants and animals on earth (see Schlegel 1984).

Bacteria cause diseases of plants as well as animals. In 1878, Burrill described the organism responsible for pear blight and, in 1883, Wakker described the bacterial cause of 'yellows' of hyacinths. Recognition of the role of bacteria in the spoilage of foodstuffs and in the production of organic chemicals useful to man led to the entrance of the bacteriologist into numerous industrial fields.

The development of 'pure' bacteriology

Pasteur's studies of fermentation in the early 1860s revealed the physiological diversity of microbes and may be looked upon as the starting-point of 'pure' bacteriological studies. During the 1870s, he became more concerned with the role of microbes as pathogens, but he continued to be interested in their basic properties. For example, in 1878, he described under the name 'Vibrion septique' a pathogenic clostridium responsible for gangrenous conditions in animals and demonstrated that it was an obligate anaerobe. Within a few years it became possible to obtain pure cultures of many sorts of bacteria by colony selection on solid media and then to

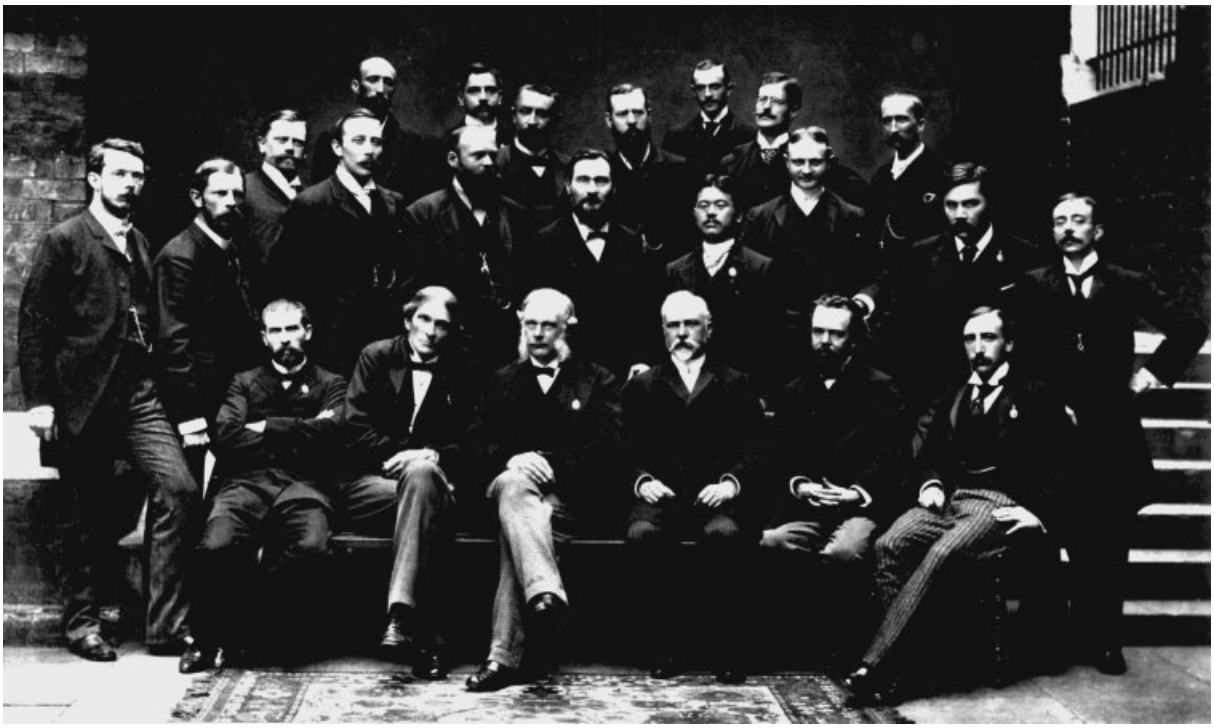

Figure 3 *Bacteriological Section, Congress of Hygiene and Demography, London, 1891.*

collect reliable data about their phenotypic characters. Accounts of their growth on various media under different physical conditions were soon supplemented by information about the range of their fermentative action on organic compounds and the products of fermentation and by the identification of chemical requirements for growth. Thus, the raw materials for systematic bacteriology began to be accumulated and basic studies of bacterial metabolism could begin.

For more detailed accounts of the early history of bacteriology, and for references, see Bulloch (1938), Clark (1961), Lechevalier and Slotorovsky (1965), and Foster (1970).

THE TWENTIETH CENTURY

The last years of the twentieth century were marked by a number of centenary retrospects; in the present context, the most important were those of the American Society for Microbiology founded in 1899 and the *Journal of Hygiene* (now *Epidemiology and Infection*) founded in 1901. Both these events resulted in the consideration of important events in microbiology, some of which are listed in Table 2 (Joklik et al. 1999; ASM 1999).

The twentieth century was the time when both pure and applied microbiology emerged as a science and produced radical developments across the whole field of biology. The most striking development has been the emergence of molecular biology and the way that this has altered our understanding of biology and medicine. This revolution is still at an early stage, but its impacts can be seen clearly in approaches to bacterial classification and typing.

SYSTEMATIC BACTERIOLOGY

Definition of the bacteria

The applied microbiologists of the time of Pasteur and Koch were not much interested in the classification of the microorganisms they considered responsible for fermentation or for communicable diseases. Contemporary biologists recognized two kingdoms of living things, plants and animals, but were uncertain in which to place the bacteria. In 1838, Ehrenberg had used the term ‘bacteria’ to describe rod-shaped organisms visible only with a microscope and considered them animals, but F. Cohn in 1854 claimed them for the botanists and Haeckel in 1866 thought that they should be placed,

along with fungi, algae, and protozoa, in a third kingdom, distinct from plants and animals, the Monera or Protista. Haeckel's view did not receive wide acceptance and for the next 50 years and more the bacteria were in a taxonomic limbo. Then, technical advances, notably the introduction of the electron microscope in 1932 and of the phase-contrast microscope in 1935, led to the recognition, usually associated with the names of Stanier and van Niel (1941), that the bacteria and certain bacteria-like blue–green algae differed from most other microbes in that their genetic material was not separated from the cytoplasm by a nuclear membrane.

This view was later formalized into the concept that there were two sorts of living things differing fundamentally in cellular structure (Murray 1962; Gibbons and Murray 1978):

1. the Prokaryotae, comprising the bacteria (Eubacteria) and the blue–green algae, which were now recognized to be phototrophic bacteria and
2. the Eukaryotae, which included fungi, algae, protozoa, and all the metazoa of the plant and animal kingdoms.

The prokaryotes were characterized by the absence of a membrane-bounded nucleus and also of cellular organelles such as mitochondria and chloroplasts. As pointed out by Woese, the definition of bacteria as nonphototrophic prokaryotes is based entirely on negative characters and provides no grounds for distinguishing the conventional bacteria from the so-called Archaebacteria. These are organisms that inhabit environmentally 'hostile' habitats and include methanogens, extreme halophiles, and thermoacidophiles; they are said to form a coherent group of organisms with characteristic isoprenoid lipids and cell-wall components (see Woese and Wolfe 1985) and to be survivals from an earlier geological era. Woese (1994) considers that genetic evidence (see section on Bacterial genetics) should take precedence over cellular anatomy in defining the relationships of the prokaryotes and eukaryotes to each other and to these primitive forms.

Classification of bacteria

Linnaeus (1707–1778) classified plants and animals according to a hierarchical system based on Aristotle's theory of logical division (see Cain 1962) by placing individuals that were alike in 'essential' characters in the same species and then constructing genera and other higher taxa on the basis of progressively greater differences in characters. The selection of essential characters ('weighting') was at first made according to the intuition of the classifier, but post-Darwinian biologists used the fossil record, often supplemented by embryological evidence, to construct classifications of plants and animals that were wholly or in part phylogenetic. This sort of evidence was not available to microbiologists and the apparent absence of sexual reproduction in bacteria meant that the biologists' favored criterion for the definition of the species, self-fertility, was denied them.

After 1880, the ability to study bacteria in pure culture led to the rapid accumulation of vast amounts of data about their phenotypic characters: colonial appearance, growth on various media, nutritional requirements, biochemical activities, serological relationships, pathogenicity for laboratory animals, and so on. Practical bacteriologists selected sets of key tests that seemed useful in identifying organisms of interest to them and in many cases attached Linnaean binomial epithets to species so characterized. What resulted was not a general classification of bacteria but a series of miniclassifications used by workers in laboratories studying medical, agricultural, or various sorts of industrial problems. There was a great deal of duplication in the naming of species, and the intuitional handling of complex collections of data led to some uncertainties in classification and identification.

NUMERICAL TAXONOMY

An alternative to seeking 'key' characters had been proposed in 1763 by Adanson, a contemporary of Linnaeus, who considered that biological classification should be based on general similarity in phenotypic characters. He rejected 'weighting' and determined, for each possible pair of individuals in a collection, the proportion of all ascertainable characters that were in accord: the so-called 'overall' similarity. Adanson found the manual computation of similarities between large numbers of pairs excessively laborious and his method could not be employed on a large scale until electronic computers became available. Then, the new discipline of numerical taxonomy was developed (Sneath 1957a, b; Sneath and Sokal 1974) and applied to collections of bacterial cultures that had been studied extensively. This made great contributions to bacterial classification at the levels of species and genus by providing an objective measure of the degree of similarity between large numbers of cultures. However, it is remarkable how often numerical-taxonomic studies supported earlier conclusions arrived at by the intuitional recognition of a 'good' classification as one that placed like organisms in the same taxon. Some taxonomists, for example Cowan (1962), expressed the view that the bacterial species was simply a man-made artifact, albeit a useful one, designed to put phenotypic data into manageable form. Numerical taxonomy provided a powerful impetus to the 'anti-essentialist' view of bacterial classification, but the practitioners of two other disciplines, chemotaxonomy and bacterial genetics, continue to search for 'key characters' that might form a basis for a broad classification of microorganisms (see Taxonony and nomenclature of bacteria).

Antigenic specificity and chemotaxonomy

In the early years of the twentieth century the antibody response to bacterial antigens had been studied intensively in vitro (Parker 1998). In the 1920s, evidence began to appear of the chemical nature of some of these antigens. This was investigated eagerly by medical bacteriologists because the antigens in question appeared to have some association with pathogenicity. Thus, a great deal of information accumulated about certain classes of antigenic macromolecules and some of this was of significance for bacterial classification.

From 1923 onwards, Avery and Heidelberger, at the Rockefeller Institute in New York, studied the type-specific capsular polysaccharides of pneumococci and showed that antibodies to them conferred type-specific immunity on experimental animals. Rebecca Lancefield, in the same laboratory, described in 1933 the so-called group polysaccharides from the cell walls of hemolytic streptococci; some of these characterized streptococcal groups that caused disease only in certain species of mammals. These polysaccharides had several characters in common:

- Though determining the specificity of the antibody response, they were unable to elicit it when separated from the bacterial body and purified; in 1921 Landsteiner coined the term 'hapten' for such molecules.
- The specificity of the antibody response to them was relatively limited. Pneumococcal polysaccharides, for example, though defining clear-cut serotypes among pneumococci, cross-reacted widely with polysaccharides of otherwise dissimilar bacteria and even with nonbacterial polysaccharides, as shown by Heidelberger, Austrian, and colleagues. This was explained by the limited repertoire of specificities provided by the sequence of sugars in the terminal part of the polysaccharide chain. The role of the terminal sugars as antigenic determinants was further illuminated by the work of McCarty and Krause on the cross-reactions between streptococcal group antigens.
- Though sometimes clearly associated with virulence, the polysaccharides were not toxic for experimental animals.

In 1943, Rebecca Lancefield described a class of type-specific cell wall protein antigens in *Streptococcus pyogenes*. Like other proteins, they were fully antigenic when extracted and purified. Antibodies to them were highly specific and conferred type-specific immunity. Though nontoxic, these M proteins determined pathogenicity by interfering with phagocytosis.

Certain other cell-bound bacterial constituents proved to have toxic properties when injected into animals. These included the endotoxins of gram-negative bacteria, first described by Boivin and his associates at the Institut Pasteur in Paris in 1932–35. These were complex macromolecules in the cell envelope comprising:

- a polysaccharide responsible for antigenic specificity
- a lipid conferring toxicity, and
- a protein that, when linked to the polysaccharide, rendered it antigenic.

Studies of the amino-acid composition of the cell walls of gram-positive bacteria by Cummins and Harris in 1956 led to the recognition by Ghysen in 1965 of the structure of their main component, the peptidoglycan or mucopeptide. In 1972, Schleifer and Kandler showed that similarities in the cross-linking of the main components of the peptidoglycan molecule were of value in establishing relationships between bacterial genera that would have been difficult to ascertain by conventional serological means. It has since been noted that all eubacterial peptidoglycans contain *N*-acetyl muramic acid but that this is absent from the cell walls of archaebacteria.

Since 1970 the chemical study of bacterial macromolecules has advanced rapidly. New information about the distribution of particular classes of lipids and isoprenoid quinones has provided grounds for establishing relationships between higher taxa of gram-positive bacteria and for distinguishing eubacteria from archaebacteria (for references see Jones and Krieg 1984).

Protein antigens, when studied by conventional serological methods, showed such a narrow specificity as to limit their value to the identification of species or serotypes. Recent studies of the chemistry of some widely distributed classes of protein, e.g. the cytochromes (Jones 1980), have revealed differences relevant to the general classification of bacteria. The increasing ability to determine the sequence of amino acids in individual proteins will add information to that provided by antigenic analysis. If a constant rate of mutation is assumed, then this might be thought to provide evidence of the evolutionary 'distance' between taxa. Such considerations may be attractive to those who favor a phylogenetic approach to bacterial classification.

Bacterial genetics

At the beginning of the twentieth century it was generally recognized that the characters of bacterial strains in culture might vary, either temporarily, in response to changes in the environment ('adaptation'), or permanently, independent of environmental conditions ('mutation'). The latter phenomenon suggested the possession by bacteria of a genetic system analogous to that of larger organisms, but proof of this was lacking in the absence of a distinct nuclear apparatus.

In 1928, F. Griffith demonstrated 'transformation' among pneumococci, that is to say, transfer to a non-capsulate strain of the ability to form capsular polysaccharide of a particular type by contact with a heat-killed culture of a capsulate strain of that type. This indicated a permanent modification of the genetic apparatus of one organism by inanimate material from another. The nature of the transforming material remained unknown until 1944, when Avery, Macleod, and McCarty showed that it was deoxyribonucleic acid (DNA).

In 1946, Lederberg and Tatum demonstrated 'recombination' between two biochemical mutants of a strain of *Escherichia coli*, each lacking different characters of the wild strain; when placed in cell-to-cell contact a strain with all the parental characters was formed. In this process, 'conjugation' had resulted in the transfer of genetic material between cells. In 1953, Hayes discovered that this was a one-way process in which a small amount of genetic material passed from a donor ('male') to a recipient ('female') cell and was thus different from sexual reproduction in plants and animals. The capacity to donate genetic material in this way depended on possession by the donor of an F (for fertility) factor.

Increasing interest in bacteriophages in the 1940s had revealed that their genetic material became incorporated into that of the bacteria they infected, and in 1952 Zinder and Lederberg showed that on occasion they might take a part of the bacterial genome with them when they left one organism and entered another, a process called transduction. Thus, by the early 1950s, it was possible to study the genetics of bacteria by exploiting the phenomena of transformation, recombination, and transduction.

Information gained from these genetic studies, together with physicochemical work on the constitution of nucleic acids, played a major role in Watson and Crick's formulation in 1953 of their hypothesis of the genetic code; according to this, the information that determines the phenotypic characters of an organism is embodied in paired linear strands of deoxyribonucleotides whose sequence in a particular region constitutes a gene. Most bacterial genes form part of a single, circular chromosome, but some are on smaller extrachromosomal closed circles of DNA called plasmids. Plasmid DNA may determine the inheritance of a single character or a few characters; examples are resistance to certain antimicrobial agents or heavy metals, individual biochemical properties, toxin production and virulence. Hayes's F factor, too, is a plasmid, one of a class of plasmids that mediate cell-to-cell transfer of genetic material, usually by means of conjugative pili.

The fact that the code is a sequence of four bases, guanine (G), cytosine (C), adenine (A), and thymine (T), had considerable significance for bacterial classification. In 1950, Chargaff had observed that, whatever the source of DNA, it contained equal amounts (in moles) of G and C, and of A and T. However, the ratio of G to A and C to T varied widely. Thus, the mol% of G + C came to be used as a measure of the genetic unrelatedness of groups of bacterial taxa. This was of most use in drawing attention to groups that were not easily distinguished by their phenotypic characters, e.g. the staphylococci and the micrococci, but had widely differing base compositions. Of course, the converse did not hold: similar base compositions did not necessarily indicate genetic 'nearness.'

Recognition that the base sequence of the DNA determines phenotypic characters suggested that it might provide the ultimate criterion for bacterial classification. At first, such sequences could be determined only in small lengths of genome. However, in 1961, Schildkraut and coworkers showed that it was possible to measure the total similarity in the sequences of the two organisms without knowing the actual sequence in either. This was done by denaturing their DNA into the single-stranded form, mixing preparations from the two organisms under appropriate conditions, and then measuring the amount of reassociation of the two strands. The amount of complementary base pairing is taken as a measure of the relatedness of the organisms. DNA–DNA pairing provided a great deal of information about the relations between organisms at or around the level of species but gave no grounds for relating the degree of homology to a definition of the species or genus. Indeed, the degree of homology within species previously defined on phenotypic grounds proved to be highly variable and proposals have been made to conflate a number of long-recognized species on the grounds of close genetic similarity.

Studies of DNA–DNA homology proved of little value in revealing broader groups among the bacteria. However, some parts of the genome, notably those coding for the production of ribosomal and transfer RNA, have come to be regarded as more 'conserved' than the rest, that is to say, to have evolved more slowly. Thus, taxonomists with a phylogenetic bent consider that studies of the homology of ribosomal RNA or of the oligonucleotide sequence on the RNA cistrons would be decisive evidence of the evolutionary 'distance' between the higher taxa of bacteria and bacteria-like organisms and thus provide a firm basis for classification (Johnson 1984).

In the eighth edition of this book it was thought that the debate between rival concepts of the phenospecies and genospecies (Hill 1990) is unresolved and perhaps unresolvable. The difference between the two schools of thought – the Lockean view that classification is a man-made device for handling information and the Aristotelian concept that the 'essence' of classification is the genetic code – was considered to be perhaps better looked upon as a philosophical rather than a scientific question.

It is a tribute to how knowledge has progressed that we now deal easily with use of molecular chronometers

for the study of relatedness and how molecules other than 16S RNA are considered for this role.

The history of some other aspects of bacteriology – the mechanisms of pathogenicity and of immunity to infection, the antibacterial agents and resistance to them, and laboratory methods of investigating bacterial infections – needs to be reassessed in the light of recent understandings. The early history of bacterial genetics was reviewed in 1990 (Cliffs and Brock 1990), but since then change has accelerated.

Writing in 1938, Bulloch considered 1876–90 as the heyday of bacteriological discovery. It is clear that he underestimated the reach, both intellectually and practically, of our discipline. Pathogens have continued to be discovered. *Legionellae*, *Campylobacter*, and *Helicobacter* are prominent bacterial examples, but it is clear that without bacteriology we would lack much of modern science. The rest of these volumes will show why.

This chapter is intended as a brief introduction to the strange mixture of science, philosophy, and formal regulation that guides the division of bacteria into named groups. This is not an unbiased account. In the Alice in Wonderland of taxonomy, nothing is quite what it seems and, as in politics and theology, opinion is an indispensable ingredient. Anyone who reads this set of volumes has reached some viewpoint on bacterial taxonomy, consciously or subconsciously. There is considerable breadth of opinion in key arguments: utilitarian versus 'natural' classification, genomic versus phenotypic versus polyphasic classification, 'splitting' or 'lumping' of taxa (Cowan 1968), and so on. This range guarantees that each microbioilogist will have found some unique position in the spectrum of opinion, and so will disagree with at least some opinions expressed here. Constructive, logical criticism and discussion would be welcome.

AN INTRODUCTORY PERSPECTIVE

The practice of medical bacteriology is founded upon the ability to distinguish between the bacteria that are isolated and to predict their pathogenicity and epidemiology from in vitro characteristics via past clinical observations in infections with closely similar organisms. This predictive capability is essential and flows from the work of many microbiologists over two centuries. Their cumulative efforts have provided the current formal species nomenclature under the aegis of the International Committee for Systematic Bacteriology (ICSB), reviewed regularly in the editions of *Bergey's manual of systematic bacteriology* (currently 2nd edition in five volumes: Garrity 2001), and a wealth of vernacular schemes. Together, these schemes provide much of the technical vocabulary of microbiology and are the basis of interpretation and prediction from laboratory tests.

In a laboratory deprived of all knowledge of the classification of bacteria, their morphological and biochemical characteristics, and the relevance of individual characterization tests, each isolate would have to be regarded as unique. It would be impossible to distinguish between pathogens and commensals, or to assess the cross-infection potential of an isolate, from in vitro tests. All available antibiotics would have to be tested for each isolate. How long would it take, for example, to untangle the characteristics of the fecal pathogens from those of gut commensals, or to rediscover the link between diphtheria and toxin-producing corynebacteria? Clearly, it would be impossible to operate under such

conditions. The laboratory would be forced to search for links between in vitro characteristics and effects on patients, to divide isolates into named groups, and so to reinvent the science of taxonomy.

Despite this key role, many diagnostic microbiologists profess a disregard for taxonomy (Magee 1993a). This attitude may derive from early specialist education, where the subject is often presented as an apparently endless list of genus and species names for rote learning, along with associated laboratory and medical characteristics. The underlying science, philosophy, and history of the subject are rarely taught; when they are, the students are often so inundated by the nomenclature and lacking in a context for their brief contact with taxonomy *per se* that these are soon forgotten. Further conscious contact with the subject is usually when rote learning is overturned by changes in the names of bacteria, for reasons that may appear obscure and irrelevant. It is therefore unsurprising that most medical microbiologists regard taxonomy as an unimportant, dull, and arcane science practiced by academics in isolation for their own edification.

This common view is grossly inaccurate but is also a self-fulfilling proposition. It builds barriers between routine microbiologists and taxonomists that limit communication and cooperation. This breaks the feedback process that is essential to the production of relevant, sensible classifications of the bacteria. Taxonomy and classifications are fundamental to all microbiological work, and an appreciation of the concepts involved is an absolute requirement for all practitioners of microbiology. Equally, taxonomists require the input of other microbiologists to direct them to areas of taxonomic confusion, to supply cultures, to moderate wilder taxonomic excursions, and, more importantly, to supply knowledge of the characteristics of the organisms in the broader context outside the laboratory.

ONE CLASSIFICATION OR MANY? THE IMPORTANCE OF CONTEXT

Cowan (1962) illustrates the range of possible classifications with the example of objects intended to join materials. He divides them first into animal (glues), vegetable (wooden pegs), and mineral (metal nails, bolts, or screws, or plastic adhesives, screws, and pins), then presents an alternative classification into solid devices and liquid glues. A dealer in scrap metals might classify these objects as ferrous, nonferrous, or nonmetal in the context of work, but quite differently in the context of repairing a broken china ornament or a broken chair. Humans have little difficulty in employing a multiplicity of overlapping, but distinct and context-specific, classifications for everyday objects. Microbiologists differ only in that most are trained to acknowledge a single formal scheme and so feel constrained to argue about its minutiae to the exclusion of other possibilities.

However, when presented with a set of clinical isolates, workers revert to practicality, happily employing classifications that have little in common with that embodied in the current edition of *Bergey's manual* (Garrity 2001). At the feces bench, isolates are divided into lactose and nonlactose fermenters, fecal pathogens and nonpathogens, aerobes, anaerobes, and microaerophiles. Staphylococci are divided in three distinct ways when dealing with blood cultures, skin swabs, or urines, reflecting experience of potential pathogenicity and the importance of further identification in the context of the specimen type, the sex of the patient, and catheterization status. Diverse gram-negative and gram-positive species are lumped together under the heading of respiratory pathogens, recognizing the need to extend this definition in the context of special cases: cystic fibrosis patients or patients on ventilators. These vernacular or 'trivial' classifications even intrude into reports in phrases such as 'coagulase-negative staphylococcus' or as multivalued context-specific phrases such as 'commensals only'.

Trivial classifications are as real and valid as those described in the successive editions of *Bergey's manual*. They exist because some worker perceived a new way of dividing bacteria that had practical use or significance, and many other microbiologists recognized the utilitarian value of the division. They reflect unavoidable deficiencies in the flexibility of nomenclature in the formal ICSB scheme, and the fact that a single classification cannot cater for all the myriad ways in which bacteria can be usefully grouped.

These trivial classifications have, by their nature, consensus acceptance and are strongly utilitarian. However, they lack mechanisms for definition and regulation of any nomenclature involved, and so are open to degradation by misuse. Terms such as 'fecal streptococcus' or 'enterobacteria' lack clear definition and are used in any of a range of senses from the all-inclusive to the restricted. Equally, these classifications tend to be restricted by their utilitarian nature to specific branches of applied microbiology.

By contrast, the formal scheme has a strictly defined, regulated nomenclature recognizable by the italicization of the formal species name. It is less robust on consensus acceptance, but it is broadly applicable in all branches of microbiology. The defined nomenclature makes this the vocabulary of choice for international and interdisciplinary communication. However, the rigidity of a defined nomenclature causes problems when changes become necessary (see below). In my view, a second context for the formal system is as a scheme supplying descriptions of the minimum-sized groups of bacteria about which one can make useful generalizations. These species definitions are the building blocks that can be assembled into larger groups in as many ways as utility demands. The ICSB provides an official system of genus and species nomenclature (Sneath 1992); by contrast the

classifications into higher taxa outlined in successive editions of *Bergey's manual* are not official (Staley and Krieg 1984) and tend to change markedly between editions.

However, the formal scheme serves many interest groups. Those who wish the scheme to supply a phylogeny of the bacteria, a 'natural' classification, or to be bent to conform with the results of a specific characterization test, or to suit the requirements of some specialist branch of microbiology would all disagree.

STACK OR FLAT: THE PRACTICAL RELEVANCE OF HIERARCHICAL CLASSIFICATIONS

Classification embraces not only the division into named species but also the further grouping of species into genera, genera into families, and so on through orders, classes, and phyla to kingdoms. This hierarchical approach has much to commend it in the classification of higher organisms. The many morphological and developmental features allow division into higher groupings in agreement with fossil evidence of evolutionary development, and, for the most part, these groups can be neatly packaged into specialist areas relevant to the applied science. However, hierarchical classification has had a more chequered history in bacteriology. Successive editions of *Bergey's manual* have portrayed gross changes in the arrangement and membership of higher taxa. Equally, each of the major applied specialist areas of bacteriology – medical, veterinary, and industrial – deals with a host of diverse bacteria whose membership could not conceivably be grouped into any exclusive 'natural' or phylogenetic higher taxon, but rather forms a diverse portion of the all-inclusive group of 'the bacteria'.

One major difficulty is the lack of nonarbitrary definitions of the taxon concept at any division from species upwards. The definition of a species concept for the bacteria has been in dispute for more than a century, and definitions of the genus, order, etc. are successively more elusive. The value judgments that set these divisions are likely to be as controversial in the new era of phylogenetic classification as they were in the days of van Niel's physiological classifications (Van Niel 1946). However, despite these difficulties, the search for a phylogenetic classification of the bacteria and other prokaryotes is of enormous importance to biology. Results from this search are likely to shape our future views on the origins of life and of the eukaryote and prokaryote forms.

For medical microbiologists, much of the turmoil in the upper reaches of hierarchical classification has remained unnoticed. Changes at genus level have affected the naming of species in laboratory reports, causing considerable inconvenience. However, the higher taxonomic divisions form a province that academics may remap with little fear of criticism from applied microbiologists, who are more interested in nomenclature and divisions at species level than in hierarchical classification.

This highlights an important, but rarely discussed contrast of attitude between academic taxonomy and applied bacteriology. The applied bacteriologist is interested almost solely in divisions at species level, and particularly in those species where identification yields an associated prediction of properties, such as pathogenicity or cross-infection potential, that cannot be examined readily or economically in the laboratory. Their requirements are for a division of the bacteria into readily identified species, each with clear and distinct properties significant to his or her application, and a stable, widely accepted species nomenclature, to allow concise communication of his or her findings. By contrast with the taxonomist, who attempts to group species in a hierarchy determined by phylogeny or similarity, the applied bacteriologist assembles species in a multitude of distinct context-specific classifications of convenience.

The single-tier classification of species nomenclature is common ground for the taxonomist and applied bacteriologist, and deserves a distinguishing name, such as the agnostic, agnarchic (by contrast to hierarchic, from the Greek root *hieros*, sacred, and *arche*, rule), or monadic (Gr. *monados*, unity) classification because of this unique unifying position. Adoption of one of these terms might eliminate the misunderstanding inherent in use of the term 'classification' to cover both the untiered division of bacteria into species, the sense in which many applied microbiologists instinctively interpret the term, and hierarchical schemes.

HISTORY AND OPERATION OF THE FORMAL CLASSIFICATION

In the early days of biology, Linnaeus understood that biologists required a concise, precise, and internationally recognized scheme of species nomenclature. He proposed a scheme of latinized binomials comprising a genus and species epithet, referring to a formal description of the species. This was universally accepted, and replaced the babel of trivial, poorly defined synonyms individual to each language with a defined vocabulary common to all biologists. This technical vocabulary now bridges language and speciality, providing an essential method of communication. Whatever other gulfs of language and misunderstanding may exist, biologists can guarantee that a species name will communicate a complex detailed description of an organism with precision, and in a remarkably concise form.

Microbes, observed earlier by van Leeuwenhoek, were assigned to six species in the class *Chaos* by Linnaeus. Work in the late nineteenth century led to the description of many bacterial pathogens and the first recogniz-

able attempt to classify bacteria by the botanist Cohn (1872). The rapid growth in species descriptions required regulation, and individual international committees were eventually set up to govern the nomenclature of animals and plants, including bacteria. Important landmarks in the advance of bacterial taxonomy were the classifications of Chester (1901), Orla-Jensen (1919), and the work of Buchanan (1918, 1925). Committees for bacterial and viral taxonomy (Murphy et al. 1995) came later, with a breakaway group covering the blue-green algae, claimed originally by the botanists and now by the bacteriologists. Regulations covering validation of new names and changes in nomenclature are embodied in codes for each of these groups, and are supervised by the appropriate international committee.

The ICSB supervises the Bacteriological Code (Buchanan et al. 1948, 1958; Lapage et al. 1973; Sneath 1992), regularly providing lists of recent validly published species names and proposed changes in nomenclature, first in the *International Journal of Systematic Bacteriology* (IJSB) and later in the *International Journal of Systematic and Evolutionary Microbiology* (IJSEM). In an effort to rationalize nomenclature, remove the burden of early errors and synonyms, and simplify access to the nomenclature, a list of the approximately 2300 historical bacterial species names considered to be valid was published as the Approved Lists of Bacterial Names (Skerman et al. 1980, 1989). This, supplemented by the subsequent IJSB/IJSEM Validation Lists, defines the current, formal nomenclature of bacterial species.

The status of this scheme is reviewed about every 10 years in successive editions *of Bergey's manual*; the current classifications for each group of bacteria are summarized by experts, and the various genera and species are described. Although there is no formal link between the ICSB and *Bergey's manual*, both clearly draw upon the same pool of expertise, and the nomenclature of the Validation and Approved Lists tend to be closely conserved in *Bergey's manual*.

There are numerous subcommittees of the ICSB, most of which deal with specific groups of bacteria and give recommendations and advice on their area. Meetings of the ICSB and of the subcommittees occur regularly, usually associated with symposia organized by the International Union of Microbiological Societies. Most of the subcommittee meetings are open, allowing participation by any interested parties.

Those wishing to propose new species or changes in systematic nomenclature must follow the rules of the Bacteriological Code if their proposal is to be considered valid. Briefly, the proposal must be published in the IJSEM, or, if it is published elsewhere, a copy of the paper must be submitted to the IJSEM for inclusion of the proposal in the Validation Lists. If a new, culturable species is proposed, then a type culture should be designated and deposited with a recognized service culture collection. Further detailed rules exist, particularly on nomenclature, and it is advisable to read the most recent version of the code (Sneath 1992) in detail before submission of a proposal. In addition, minimal acceptable standards for species descriptions are being formulated (Lévy-Frébault and Portaels 1992; Ursing et al. 1994; ICSB Subcommittee on the Taxonomy of Mollicutes 1995), and the standards for the appropriate group should be consulted. Provisions for proposed species that are (currently) nonculturable but have been characterized by DNA sequencing have recently been clarified (Murray and Schleifer 1994; Murray and Stackebrandt 1995). Recent advice on characterization methodologies and the definition of the species level is presented by Stackebrandt et al. (2002). This paper reiterates the advice of Christensen et al. (2001), who argue that a species proposal should be based on the description of more than one and preferably at least five to ten strains.

THE PROCESS OF CLASSIFICATION

This begins with the selection of a limited series of isolates that appear to show restricted diversity (Figure 1). This is simplification by selection, and requires an intuitive recognition of probable groups. Inclusion of a range of reference and type cultures, and of many strains isolated from a broad range of sources, is advisable. The strains are then characterized in a large number of selected tests, producing descriptions for each. These descriptions are compared, either by calculation of a coefficient of similarity for each pair of isolates in numerical taxonomy (Sokal and Sneath 1963; Sneath and Sokal 1973), or intuitively. From these similarities, the existence of sets of isolates or taxa is postulated. It is desirable that the taxa should be cohesive and differentiable, i.e. that the differences between taxa should be greater than the variation within a taxon.

The taxa are then described and named, according to the rules of nomenclature (Bousfield 1993; MacAdoo 1993), allowing the cohesive (least variable) portions of the description to be communicated in the shorthand form of a name. There are some minor, but irritating problems with the current nomenclatural system. There is no maximum length in characters for a species binomial, but long species names can tax those installing computerized reporting systems. In the absence of an ICSB ruling on this, authors proposing new nomenclature should be mindful of the problem and avoid imposition of this inconvenience on their colleagues. Also, there is no nomenclatural guidance on standards for abbreviation of generic names, e.g. *Str*. for *Streptococcus* or *Streptomyces*, and this may be a problem in wide ranging papers, or general texts.

Finally, new isolates can be identified, i.e. named as being members of one of the postulated taxa, on the basis of their similarity to the taxon description, or to

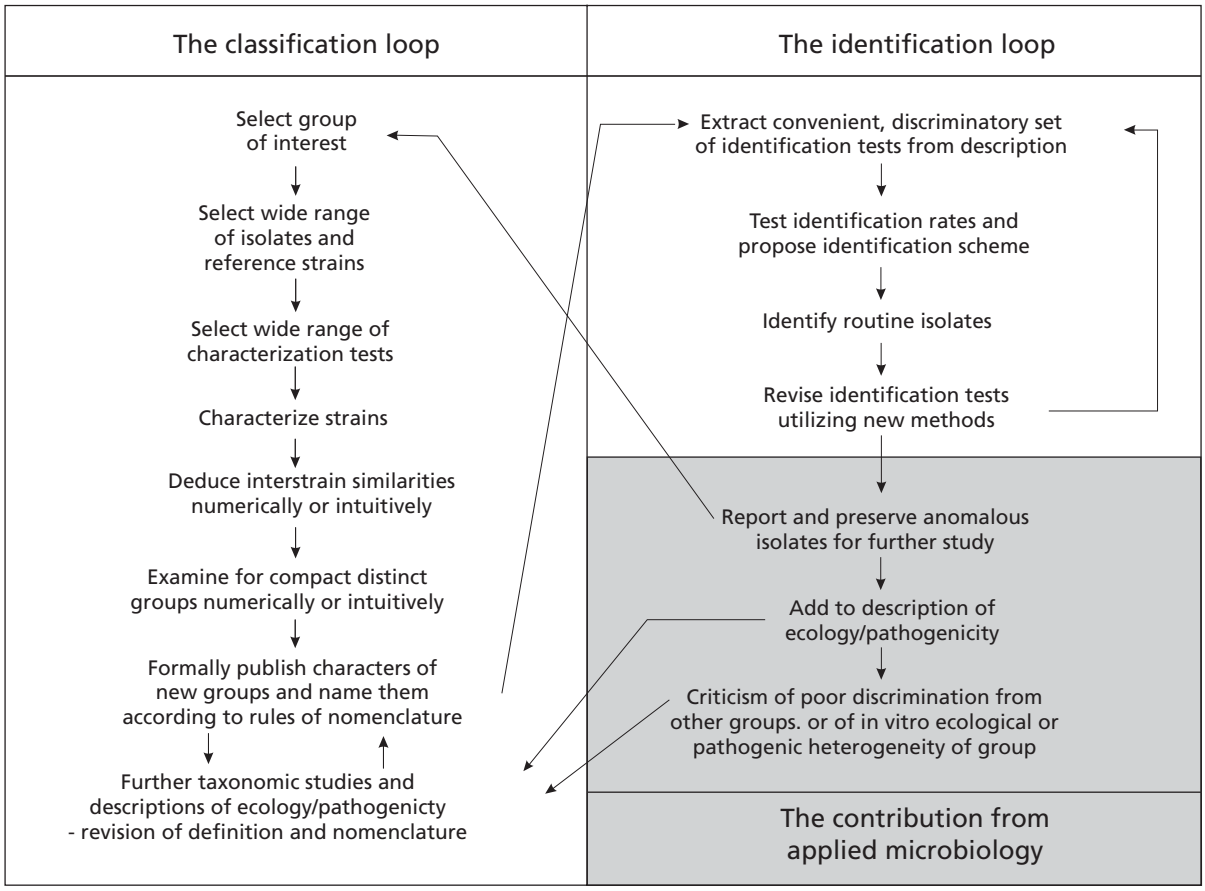

Figure 1 *The taxonomic process represented as a flow diagram.*

exemplar members of the taxon (type and reference strains). The taxon description will often have been enlarged by this stage. In particular, evidence on properties too difficult, time-consuming, or costly to assess in initial tests may have accumulated. In microbiology, this will often include a mass of anecdotal evidence ascribing particular pathogenic, ecological, or spoilage properties to a species. This evidence is a key ingredient in the prediction of significant pathogenic (and other) properties from identification, transforming a new taxon from the arena of solely academic interest to that of significance in applied bacteriology. New tests that are more convenient, reliable, or rapid may have been shown to differentiate the species. Usually, fewer tests are applied in identification than in classification; only those that have proved reproducible, discriminatory, convenient, and inexpensive are used. Note the crucial distinction between classification, which seeks to elucidate a group structure, and identification, which seeks to assign new isolates to an appropriate group within an existing classification.

IDENTIFICATION

There are three broad approaches to identification in general use. The first, and most important, is recognition of colony morphology (and its variation over a range of isolation media) by an experienced microbiologist, sometimes with confirmation by a few rapid, simple tests. This is the basis on which most clinical isolates are divided into commensals or contaminants of no interest, possible pathogens, and probable pathogens. Without this rapid triage of isolates, most diagnostic laboratories would be faced with an overwhelming workload of formal identification. However, the apparent simplicity of the process conceals much complexity and has far-reaching consequences upon the practice of medical microbiology.

Intuitive human pattern recognition is notoriously difficult to document, is impossible to teach in a formal setting, and requires prolonged training, strong perceptive and intuitive talents, and considerable intelligence. This shapes a long training process of one-to-one teaching at the bench, with either tight selection or a high failure rate. Equally, the triage of isolates must be performed or checked by those with great expertise and experience. The screening process is an art, rather than a science; however, it is difficult to justify the expense of the costly but essential training in this art to paymasters. As in the production of hand-crafted furniture, the quality of the reports that a

laboratory generates depends heavily on the expertise, skill, and time that staff can devote to each specimen. Surprisingly, there appears to be no study in the literature that documents the error rate of this process; whether this reflects an unquestionable accuracy, overweening ego, a profound fear of the consequences of documenting errors, or simple omission is difficult to ascertain.

After this triage, formal identification is performed upon potentially significant isolates. In earlier times this often used an 'identification key,' exemplified by the identification scheme for coagulase-negative staphylococci proposed by Kloos and Schleifer (1975). The key is a tree-like logic diagram, with a test name noted at each branch point, and two branches (one for isolates that are positive, and the other for isolates that are negative in that test) indicating the further logic pathway for identification. The investigator follows the logic tree to a terminal branch, where the designer of the key has decided that sufficient similarity has been established for identification and noted the appropriate species name. This was the favored approach in the early editions of *Bergey's manual*, and in the various earlier schemes (Chester 1901; Orla-Jensen 1919), reflecting the lasting botanical influence on early bacterial taxonomy. Keys depend heavily upon invariant characteristic reactions, although the later efforts, particularly the Kloos and Schleifer scheme, make some allowance for test variation. However, the work of numerical taxonomists brought general acknowledgment that bacterial species are polythetic, i.e. any individual property may vary within a species. Only the most sophisticated and complex keys could cope with this variation, and, with the introduction of numerical identification, formal keys have declined greatly in importance.

Numerical identification is based on surveys that define tables of the expected frequency of positivity in a series of tests for each species. The reaction pattern of an'unknown' isolate is compared with this table, and its 'goodness of fit' with each species is determined. This comparison may be intuitive, as in the early schemes (Castellani and Chalmers 1919; Enterobacteriaceae Subcommittee 1958; Cowan 1956) and in the tables of the various editions of Cowan and Steel's classic identification manual (Cowan and Steel 1965), or by formal mathematical comparisons. The latter may be calculated concurrently by computer programs, or the calculations may be performed earlier, giving lists of common reaction patterns with the best-fit identification for each, as in the various identification listings for API identification kits. The underlying mathematical principles are described in the classic paper of Willcox et al. (1980) on numerical identification.

In contrast to classification, where a host of ill-defined mathematical assumptions must be made during data processing, the mathematical identification strategies described by Willcox et al. (1980) rely on only six clear prior assumptions. These are that:

1. the isolate under study cannot be a member of more than one taxon
2. the isolate is a member of a known taxon
3. each of the tests employed yields a result that varies independently of all others
4. the tests have roughly equal within-strain reproducibility
5. this within-strain reproducibility does not vary significantly between species or strains
6. the tests yield clear negative or positive results.

Two important parameters in assessing numerical identifications are the 'strangeness' or absolute likelihood of obtaining the observed pattern, often assessed as the estimated frequency of occurrence, logarithmic probability, or modal likelihood fraction, and the 'equivocality' or relative likelihood of the fit with known result patterns, often assessed as a percentage relative likelihood or 'identification score'. The 'strangeness' index is calculated for each known species (Table 1), and the species with the highest index is chosen as the best-fit identification. Caution is required if the strangeness index is low. This indicates that the observed pattern of reactions is most unusual, even for the best-fit species, and the isolate may well be a 'stranger' – a member of a new species or a species not listed in the table. The equivocality index indicates the level of uncertainty in ascribing the isolate to the best-fit species if it is not a 'stranger'. Again, if this index is low, then the identification is uncertain, split finely between two or more species, and it would be wise to proceed to further tests, particularly if the identification equivocates between species of significantly distinct pathogenic or cross-infection potential.

A common reason for unusual reaction patterns is that the culture is impure; close examination of prolonged subcultures on a wide variety of media, incubated under a range of conditions, will often reveal cryptic contaminants in these cases. Equally, isolates of *Bacillus* or *Clostridium* species that are asporogenous and show a negative gram-staining reaction present an insidious trap for the unwary, who may waste considerable effort under the false assumption that these organisms are true gram-negative bacilli. Conclusive proof of the true nature of such isolates may be difficult to obtain, although colony morphology often provides an indication of the problem.

Ascribing a species name to an isolate should be a carefully considered action. The name will usually communicate an implicit description of many properties that have not been, or cannot be, examined in the laboratory. Once identified, the isolate will be assumed to possess all these implied properties, whether these describe biochemistry, pathogenicity, capability of cross-infection, etc. A poor identification, arrived at with

Table 1 *Mathematical identification: a worked example*

a) Determine reaction pattern of unknown isolate in tests T1 to T7:

Test	T1	T2	T3	T4	T5	T6	T7
Result	+	+	–	+	–	+	+

b) Refer to a reputable identification table

	Known frequency of positive reactions in test:							Maximum
Taxon	T1	T2	T3	T4	T5	T6	T7	likelihood
A	.99	.01	.99	.01	.99	.99	.99	.932
B	.99	.75	.01	.90	.75	.90	.10	.442
C	.90	.85	.10	.95	.05	.99	.99	.609
D	.95	.99	.99	.99	.95	.01	.01	.858
E	.01	.01	.05	.01	.99	.01	.99	.894

The maximum likelihood is calculated for each taxon from the reaction pattern that yields a 'perfect' fit to that taxon (sequentially multiply 1−frequency for tests with frequency ⩽0.5, or frequency for tests with frequency >0.5; see below in c).

c) Calculate the likelihood of obtaining the isolate pattern for each taxon

For each taxon, calculate the likelihood by multiplying the frequencies for each test together, but substituting (1−frequency) for the frequency if the test result is negative

Taxon	Likelihood calculation		Likelihood
A	$.99\times.01\times(1-.99)\times.01\times(1-.99)\times.99\times.99$	=	9.70×10^{-9}
B	$.99\times.75\times(1-.01)\times.90\times(1-.75)\times.90\times.10$	=	$\mathbf{.147\times10^{-1}}$
C	$.90\times.85\times(1-.10)\times.95\times(1-.05)\times.99\times.99$	=	$\mathbf{.609\times10^{-1}}$
D	$.95\times.99\times(1-.99)\times.99\times(1-.95)\times.01\times.01$	=	4.66×10^{-9}
E	$.01\times.01\times(1-.05)\times.01\times(1-.99)\times.01\times.99$	=	9.41×10^{-11}
	Sum	=	.756

d) Calculate the 'strangeness' indices, negative log probability, and modal likelihood score, which indicate how unlikely the test result pattern is for each taxon. Calculate the 'equivocality' indices, identification score, and relative likelihood, which indicate the equivocality of the best-fit result

	Negative log probability			Modal likelihood score		
Taxon	Calculation		Result	Calculation		Result
A	$-\log(9.70\times10^{-9})$	=	8.10	$9.70\times10^{-9}/.932$	=	1.04×10^{-8}
B	$-\log(1.47\times10^{-1})$	=	.83	$1.47\times10^{-1}/.442$	=	**.33**
C	$-\log(6.09\times10^{-1})$	=	.22	$6.09\times10^{-1}/.609$	=	**1.00**
D	$-\log(4.65\times10^{-9})$	=	8.33	$4.66\times10^{-9}/.858$	=	5.42×10^{-9}
E	$-\log(9.41\times10^{-11})$	=	10.03	$9.41\times10^{-11}/.894$	=	1.06×10^{-10}
	Identification score			**Relative likelihood**		
Taxon	Calculation		Result	Calculation		Result
A	$9.70\times10^{-9}/.756$	=	1.24×10^{-10}	$9.70\times10^{-9}/.609$	=	1.59×10^{-6}
B	$1.47\times10^{-1}/.756$	=	**.194**	$1.47\times10^{-1}/.609$	=	**.24**
C	$6.09\times10^{-1}/.756$	=	**.805**	$6.09\times10^{1}/.609$	=	**1.00**
D	$4.65\times10^{-9}/.756$	=	6.16×10^{-9}	$4.66\times10^{-9}/.609$	=	7.65×10^{-9}
E	$9.41\times10^{-11}/.756$	=	1.24×10^{-10}	$9.41\times10^{-11}/.609$	=	1.55×10^{-10}

e) Conclusion

All scores for taxa A, D, and E indicate extremely poor fit. The taxon most likely to yield this result pattern is C. The identification score is poor at .805 (values appraoching .99 are desirable), but this is expected with such a small number of tests that yield mostly variable results for this taxon. Correcting for taxon variability (division by the maximum likelihood for taxon C) yields a modal likelihood score of 1.00, indicating that no better fit can be obtained for this taxon with limited tests chosen. However, the 'equivocality' indices both indicate an equivocal identification, with the fit to taxon B being only one-quarter less likely than the fit to taxon C. The poor identification score and high equivocality indicate that this isolate requires further tests suited to discriminate between taxa B and C to produce a reliable identification result.

much equivocation, can acquire an undeserved aura of precision during the reporting process. In these cases it might well be more accurate to state that the isolate is unusual, and although most similar to the best-fit species, may well not share all the species properties.

Further, the perception of the properties implied in the species name will vary between individuals, according to their knowledge of systematics and the biases imbued in training and specialization. This is a problem of the 'shorthand' communication of data via a species name, which requires good to perfect agreement between the communicating parties on the definition implied in the species name. Clearly, the level of agreement on the implied description may well be unsatisfactory if one side is employing a current nomenclature and description, while the other has little contact or interest in microbiology and is struggling to remember information from a minor part of a syllabus learned decades before. The laboratory cannot assume that clinicians will understand the full implications of a species name for any but the most frequently encountered species and should take every opportunity to expand upon the properties that are intended to be communicated to the recipient. The possibilities of gross distortion of important clinical implications in this communication have become ever greater with reductions in resources, increasing time constraints, and the increasing speed of change in species nomenclature.

CHARACTERIZATION TESTS

The lack of a nonarbitrary, generally accepted definition of the species concept in bacteria (see below) inevitably, but wrongly in my view, directs bacteriologists to definitions based on some particular characterization technology. A broad description of the various technologies is given below and in Table 2. Note that none of these methods yields results that can be considered invariably to give the isologous comparisons of truly independent variables required in taxonomy.

Microscopic morphology

These characters comprise: cell shape, size, arrangement, staining, motility and capsule characteristics, spore position and morphology, and flagellar arrangement. Electron microscopy extends these somewhat to fimbriation, wall and cytoplasmic structures. Early microbiologists of the van Leeuwenhoek era were limited to describing the cell morphology and ecological occurrence of those few groups of bacteria distinguishable on the basis of light microscopy. Macroscopic organisms show a massive range of readily observed distinct morphological characters, sufficient to distinguish a huge number of groups. However, bacteria, at the limit of resolution in light microscopy, can be divided into few groups on the basis of cell morphology.

This may have been a major factor in forming a sharp difference of attitude between bacteriologists and macrobiologists. While eighteenth- and nineteenth-century botanists and zoologists sought to document the diversity of macroorganisms, ranging throughout the world in their search for specimens and describing hundreds of thousands of species, bacteriologists centered their work on groups that were involved in disease or had industrial importance. With few exceptions, bacteriologists did not participate in the eighteenth- and nineteenth-century 'collection fever' phase of biology because bacterial characterization was still primitive. By 1989, only about 2300 bacterial species were cited in the Approved Lists, indicating a combination of the low level of interest in discovery and documentation of new taxa during the previous century, and the difficulty of these tasks.

Table 2 *Characterization methods: features dictating their practical utility*

Method	High speed	Good throughput	Low skill	Automated	Low costs		Differentiation level
					Capital	Running	< Genus Species Type >
Ecological	-	-	-	---	++	--	<<---------->
Morphological	++	++	-	---	+	++	<<----->
Colonial	+++	+++	+	---	+++	+	<<---------->
'Biochemical'	+	++	++	p	++	++	<<---------->

Key: -, --, ---, increasingly less favorable; +. ++, +++, increasingly more favorable; p, possible; s, some.

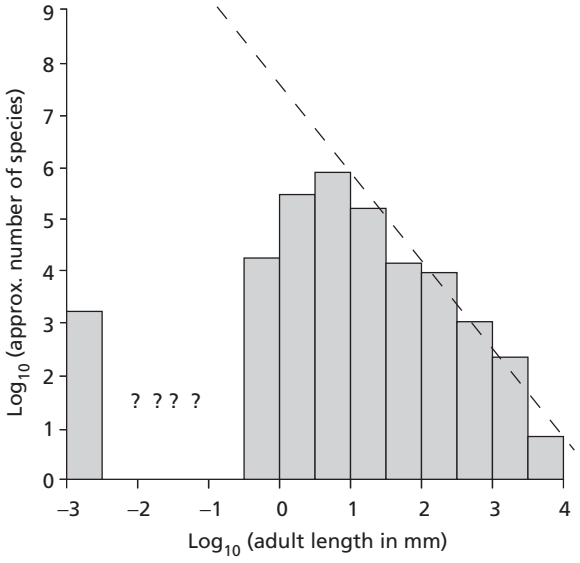

Figure 2 *Histogram representing the number of known species vs adult size. The dotted line indicates proportionality of the number of species with the inverse square of adult body length (modified from May 1988).*

This omission is reflected in the often-cited histogram (Figure 2) of the number of known biological species versus adult size. The diagram shows a maximum number of species at a size corresponding to the limit of resolution of the human eye. This may well be an artifact of limited endeavor. The approximately 5000 currently described species of bacteria probably represent a tiny fraction of bacterial diversity, a contention supported by recent studies of 16S rRNA diversity in natural environments (Stackebrandt et al. 1993; Liesack and Stackebrandt 1992).

Colonial morphology

With the invention of solid media and pure culture techniques came colonial morphological characters. For an experienced bacteriologist, the wealth of data from this source is often sufficient for identification at genus or finer taxonomic levels. Most isolates that are discarded in routine diagnostic work as not clinically significant are identified solely on this basis. However, although often highly discriminatory, particularly after prolonged incubation, the many subtle characters involved are often medium- and incubation-dependent and are notoriously difficult to document. Taxonomists should not ignore this elementary investigation, which will often delineate important divisions within a collection of strains and is crucial to exclusion of impure cultures.

Biochemical tests

Early experiments on optimization of medium composition and incubation conditions led naturally to assessment of nutritional characteristics. The so-called 'biochemical tests' that evolved became an essential tool in bacterial taxonomy and identification. These include tests for fermentation or oxidation of sugars; waste products; metabolism of organic acids, proteins, amino acids, and lipids; temperature, pH, and redox range for growth or survival; and tolerance of various chemical agents. In short, they collectively define the nutritional and physiological interactions of the organism with its environment.

These tests are usually technically simple, are inexpensive, and have high throughput when adapted to multipoint inoculation, commercial test strip, or microtiter plate formats. Most yield bi-state, i.e. positive or negative, results that are convenient to read. However, it should be recognized that these bi-state results usually represent a simplification of a more complex situation.

As an example, the test for production of acid from sugars measures a fall in pH, separating as 'positive' those strains that produce sufficient excreted acidic metabolites to reduce the pH below a threshold where the indicator dye changes color. Measuring the pH of the culture (Figure 3) may reveal more complexity, with distinct groups that produce a large, moderate, or small fall in pH, no change, or even a rise in pH. On further examination, the results of the test depend upon many factors: the threshold at which the indicator changes color; the buffering capacity of the medium; the concentration of the sugar; the amount of acidic products excreted; the strength (pKa) and hence molecular structure of the acidic products; the parallel production of alkaline products (e.g. production of ammonia from amino acids or peptides in *Bacillus* and *Clostridium* spp.); the further metabolism of the acids; and the loss of volatile acids from the medium.

Clearly, the technical simplicity of this test conceals far-reaching complexity. Strains that produce small amounts of acetic acid, and others that produce large amounts of caproic acid, may both yield positive results,

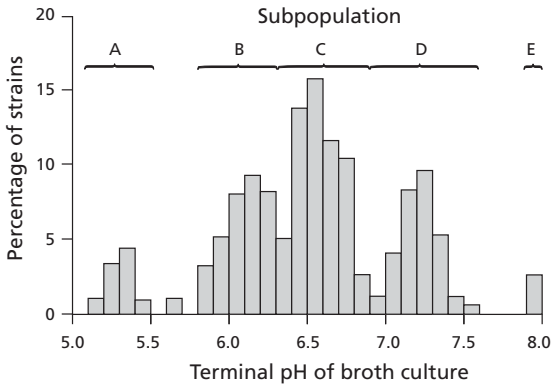

Figure 3 *Terminal pH of sugar-containing media: a histogram for 420 strains of anaerobic gram-negative bacilli showing multiple distinct populations (unpublished data provided by Prof. B.I. Duerden).*

because the quantitative difference is balanced by the qualitative difference in the nature and therefore strength of the acids. Equally, organisms with identical glycolytic pathways, but differing in the presence of a tricarboxylic acid cycle and an electron-transport chain capable of converting stronger acidic products to weakly acidic CO_2, would differ in their acidification of aerobic glucose-containing media. Strains with similar biochemistry may differ in their ability to acidify glucose-containing media, and strains with distinct biochemistry and end-products may yield identical results. In taxonomic studies, comparisons are assumed to be of isologous characters, yet acidification tests may reflect anything from a remote ecological similarity in acidification of sugar-containing environments, to truly isologous biochemistry.

A further problem results from this 'thresholding' of biochemical tests. Equivocal results and test irreproducibility are likely to be a problem if the test threshold does not coincide with a population minimum. In Figure 3, a detection threshold pH of 5.5 coincides with a minimum in the population distribution. A threshold at this level would give few equivocal results. However, a threshold at pH 6.2 would coincide with a subpopulation maximum, giving many equivocal results, and a division into positive and negative groups that would not reflect real underlying similarities in the biochemistry for subpopulation B. In practice, these thresholds are defined by the buffering capacity of the test medium, the pH range for color change in the indicator, and the concentration of the substrate.

Formal proof of adequate thresholding is rare in biochemical tests, but the range of genus-specific basal medium and indicator system formats of, for example, sugar acidification tests clearly indicates intuitive recognition of the problem. Finally, strains that give delayed metabolism of acid products or produce highly volatile acids may yield an early positive result but revert to negative on prolonged incubation.

Morphological, colonial, biochemical, and enzyme detection tests are the basis of current routine identification technology. For routine bacteriologists, it is essential that any species or genus name reaching the Validation Lists should have a description of these characters that allows clear identification and discrimination from similar taxa. Applied microbiologists have a clear interest in ensuring that this principle is a central feature of the minimal descriptions formulated by the ICSB committees to direct taxonomists on a line that is compatible with the current requirements of routine laboratories.

Tests for enzyme activity

Further characterization strategies were investigated. Research showed that some pathogenic effects of bacteria were due to toxins. These toxins included exoenzymes, and an offshoot of this work was a clear lineage of characterization tests based on detection of individual enzymes, from the early tests for proteolytic and lipolytic activity to the modern preformed enzyme tests (Manafi et al. 1991; James 1994). This line produced major advances in biology. Monod's work on the lactose fermentation system of *Escherichia coli* laid the foundations of our understanding of underlying control mechanisms of the cell biochemistry of all living things.

The trend in bacteriology from morphological to physiological and biochemical characterization contrasted with that in macrobiology. Here, morphology still retained practical precedence, but phylogeny, classification based on the postulated evolutionary history of organisms, was becoming a target for academic biologists. Bacteriologists, driven by a paucity of morphological characterization tests, and lacking the fossil material required for phylogeny, resorted to ever more biochemically oriented characterization technology. It is ironic that this technology ultimately led to the precedence of bacteriology in the discovery of DNA as the substance governing inheritance, and in much of the molecular biology that flowed from that event. Bacteriology, which had largely turned its back on phylogeny, provided the basis for the nucleic acid sequencing methods so essential to modern molecular phylogeny.

Chemotaxonomy

Early work on immunology produced serological characterization tests (Bowden 1993). Interest in the chemical basis of these tests, and work on the mode of action of beta-lactam antibiotics, gave a detailed understanding of the chemical structure of bacterial cell walls. The remarkably diverse structures that were found correlated with other properties. Crucially, this clarified grouping of genera into families and laid the foundations of chemotaxonomy, the examination and comparison of cell macromolecules. This approach to characterization has become steadily more important in taxonomy (Goodfellow and O'Donnell 1994).

Methods include comparison of cell-envelope macromolecular structure, particularly the murein polypeptide links, teichoic and teichuronic acids, and polar and nonpolar lipids (Hancock 1994; Embley and Wait 1994); electron-transport-chain components of oxidative and photosynthetic metabolism, the quinones, cytochromes, and bacteriochlorophylls (Collins 1994; Poole 1994; Richards 1994); and overall base ratios of DNA (Tamaoka 1994). For the most part these are costly, slow, low-throughput methods requiring considerable expertise, but they provide detailed chemical information relevant to classification at species, genus, and suprageneric levels.

Fingerprinting

Another characterization technology related to chemotaxonomy is termed 'fingerprinting'. The methods include sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis of proteins (Vauterin et al. 1993; Pot et al. 1994), pyrolysis mass spectrometry (Hindmarch et al. 1990; Goodfellow et al. 1994), whole-cell matrix-assisted laser desorption ionization–time-of-flight (MALDI-TOF) mass spectrometry (Claydon et al. 1996; Lay 2001), and others of less familiar nature (Nelson 1991; Magee 1993b, 1994). These investigations yield results that reflect the chemical composition of the cell, but in comparative terms rather than by elucidation of detailed chemical structure. Fingerprinting methods utilize rapid physicochemical separation methods that produce profiles that can be compared to allow detection of similarities between strains. The profiles are often complex; the underlying nature of differences cannot be deduced from fingerprinting alone; and the methods are often based on costly instrumentation. However, these methods usually have a high throughput, automated processing, and low running costs, and produce many data relevant to cell composition, a facet that is otherwise difficult, slow, and costly to investigate. These data are pertinent at taxonomic levels from subspecies to supragenus.

Molecular genetics

The first inroads into DNA-based bacterial taxonomy came with assays for the ratio of guanine-cytosine (GC) to adenine-thymidine (AT) pairs in DNA (Tamaoka 1994), detecting the frequency of usage for GC-rich codons. The G+C content of bacterial DNA varies widely across the genera (see Tamaoka 1994), but less so within a genus. This is a useful tool to detect heterogeneity at genus level. Although significant differences clearly indicate dissimilarity, close similarity of G+C content does not necessarily indicate close similarity in other properties. Clearly, although the proportion of base pairs may be similar, the base sequence of the DNA may differ widely and code for a distinct metabolic pattern.

Later, DNA-DNA hybridization techniques allowed comparison of base sequence compatibility between strains (Kreig 1988; Johnson 1991; Stackebrandt and Goebel 1994). In this, DNA from a marker strain is annealed with DNA from the strain to be compared, and unbound DNA is removed. The extent of heterologous duplex formation indicates the extent of matching base sequences between the marker and test strain. As a control, 100 percent sequence compatibility is assessed by hybridization of marker and test DNA from the same strain. Annealing is performed under stringent conditions, at a high temperature, ensuring that only fragments with close sequence similarity remain bound, and at a lower, nonstringent temperature, where fragments may bind despite deletions and point-base differences.

Hybridization is currently recognized as the definitive test for similarity in bacteria. Strains showing more than 70 percent binding under stringent conditions with less than 5 percent difference between binding under stringent and nonstringent conditions are considered to belong to the same species (Wayne et al. 1987). Binding at this level indicates about 96 percent sequence identity (Stackebrandt and Goebel 1994). Anomalies between hybridization results and biochemical classifications occur in *Pseudomonas* (Roselló et al. 1991), the *Enterobacteriaceae* (Gavini et al. 1989), and *Bacillus* (Priest 1993).

However, hybridization is a prolonged, low-throughput approach requiring considerable expertise, and hampered by technical difficulties (Sneath 1983; Hartford and Sneath 1988; Johnson 1991) and potential distortion where repetitive sequences occur. Heteroduplex formation decreases markedly at supraspecies levels, and no inferences can be drawn on similarities at genus or further levels. Schleifer et al. (1993) have developed a rapid-lysis blotting hybridization system suited to identification.

Comparison of the base sequence for specific genes, usually that coding for the 16S rRNA of the small ribosome subunit, has become a standard approach. Various methods are available, including the original technique of direct sequencing of the 16S rRNA (Donis-Keller et al. 1977; Peattie 1979; Stackebrandt and Liesack 1993), but most groups currently utilize the polymerase chain reaction (PCR) to amplify a gene segment between two highly conserved sequences suited to PCR priming and DNA sequencing of the product.

The 16S rRNA gene is eminently suited to sequencing by this approach, as it contains 3′ and 5′ sequences that are virtually identical in all bacteria, are a suitable size for priming, and are separated by a sequence of a size (approximately 1.5 KB) that is readily copied by the PCR. Further, it is suggested that much of the sequence is highly conserved and so is unlikely to be subject to strain variation. Databases of known 16S rRNA sequences are available on the world wide web, notably on www.bdt.org.br/structure/molecular.html. Strains of the same species show sequence similarities greater than 97 percent. However, strains showing similarity at or above this level may belong to distinct species as defined by DNA hybridization (Ash et al. 1991; Fry et al. 1991; Fox et al. 1992; Martinez-Murcia et al. 1992; Stackebrandt and Goebel 1994). Advances in the technology have made 16S rRNA sequencing available as an identification method used in reference laboratories for particularly difficult strains. It is considerably less demanding in time, expertise, and cost than DNA hybridization.

Despite its current popularity, there may be several problems with 16S rRNA sequencing. Flawless transcription of a sequence of about 1500 base abbreviations to paper or computer file is no mean feat and the inevitable errors in proofreading these transcripts become embedded in the literature. This is no small source of inaccuracy, as noted elsewhere (Meissner 1995; Bernard et al. 1995). Sequences determined for the same species, or even the same strain, by different groups can differ significantly (Clayton et al. 1995). The source of these differences could be sequencing errors, intraspecies variation, or as many species contain multiple copies of the rRNA operon, interoperon differences. Several methods have been used in sequencing and the copy error level with different enzyme preparations is known to differ. Small differences in error rates or bias in the types of error from either source could lead to significant sequence differences. A level of about 3 percent sequence difference is suggested as a species cut-off, yet 18 percent of sequence pairs determined independently for the same strain differed by more than 1 percent in the study of Clayton et al. (1995), and 8 percent differed by more than 2 percent. Clearly, the overall error level in deposited sequences is close to the natural variation between closely similar species.

The sequence of individual product DNA molecules copied in PCR may differ slightly from that of the original template, or the operon copied may be atypical. With low-error-rate polymerase, these erroneous products are unlikely to affect direct sequencing of the pooled product. However, some groups select a single product molecule by cloning into a plasmid for later sequencing, and there is a possibility that an atypical product may be selected in cloning. A large blind-coded interlaboratory study to define the accuracy of sequence determination for the various methods and modifications and an effort to weed out or confirm any possibly inaccurate sequences in the databases would greatly enhance the utility of this approach.

The 'black-box' approach to numerical analysis that is evident in many papers on 16S rRNA sequencing has also been criticized. Goodfellow et al. (1997), reviewing a single issue of IJSB, found clear deficiencies in the numerical methods section of six papers on sequencing. Numerical analysis of similarity data is a complex subject unsuited to black-box processing. The deficiencies are highlighted by comparison with work on other characterization techniques, where data are often analyzed with four or more distinct numerical approaches and the homogeneity of the proposed consensus groups is then examined to verify the conclusions. Sequence data present greater difficulties in numerical analysis than most other characterization data. There are problems of alignment around deletions and insertions and in the interdependency of base sequences in distinct regions that hydrogen-bond together to form a functional tertiary structure. Sequence data require more effort in numerical analysis, and more caution in interpretation, rather than less. Unfortunately, the rise in availability of numerical taxonomic computer programs has encouraged cursory analysis, without the underlying understanding and caution required for interpretation.

Having said this, gene sequencing has opened the possibility that the evolutionary descent (phylogeny) of the current range of bacterial species may be determined. A phylogeny based on the 16S rRNA gene is now well-advanced (Woese 1987, 1992, 2000). This has had a major influence on the classification presented in the latest edition of *Bergey's manual* (Garrity 2001) and the few studies based on sequences of other conserved genes seem to verify this phylogeny.

Polyphasic taxonomy

Each of these individual characterization approaches has been hailed in its time as the last great advance in taxonomy, the discovery that would put every bacterium in to its proper place in a 'natural classification.' After experiencing four such 'revolutions,' I have come to a more moderate view. Each approach has its individual advantages and disadvantages. Each gives a different, and sometimes contrasting, insight into the differences between bacteria. Each has its place in taxonomic research and identification. Together, the results of all these approaches should give a robust general classification. The deficiencies of low-throughput, high-cost methods can be offset by testing the typical members of clusters detected in high-throughput, low-cost techniques. High-throughput techniques are suited to the search of large strain collections for potential new species.

Taxa that are distinct and cohesive in the large range of current techniques should stand the test of time. Colwell (1970) first suggested this polyphasic approach. However, despite its unarguable logic and repetition of the simple message by many experienced bacterial taxonomists, papers suggesting major taxonomic revisions based on a single technique continue to appear, only to be debunked later. The increasing instability of nomenclature at genus level in some areas of bacterial classification may well reflect the failure of workers to implement this polyphasic approach. A craftsperson uses many tools to fashion a useful object; taxonomists should recognize that each of the many approaches to characterization has an individual appropriate use in construction of classifications. Although a classification can be based on a single characterization method, it is unlikely to be of general use.

VISUALIZING THE RESULTS OF A CLASSIFICATION STUDY

Presentation of results is one of the greatest problems in taxonomy. Most authors choose diagrammatic representations – dendrograms, rooted or unrooted

trees, or occasionally two- or pseudo-three-dimensional ordination diagrams (Figure 4). Each has advantages and disadvantages, but none can represent the full complexity of the data. The alternative tabular presentations (Figure 4) – full or shaded similarity matrices – show the full data but are unwieldy and difficult to interpret. Many applied microbiologists do not have the knowledge to interpret the subtleties of these diagrams, and many would-be taxonomists use the programs that generate these diagrams as black boxes, in ignorance of the principles and shortcomings of the calculations involved (Goodfellow et al. 1997).

The dendrogram (Figure 4a) has a single axis indicating similarity between strains or between groups.

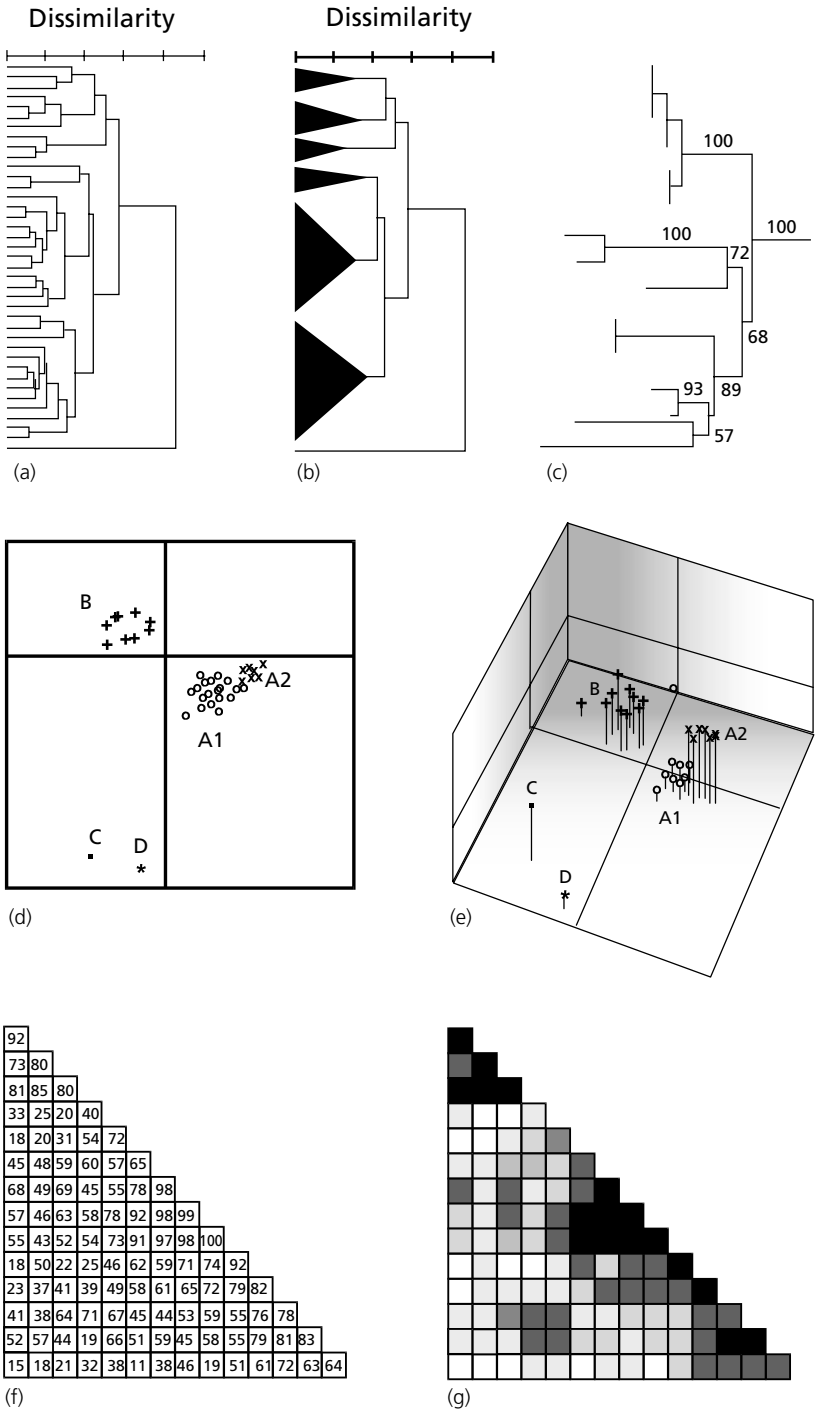

Figure 4 (a–g) *Representations of taxononomic data:* **(a, b)** *dendrograms;* **(c)** *tree (phenogram);* **(d)** *two-dimensional ordination;* **(e)** *pseudo-three-dimensional ordination;* **(f)** *similarity matrix;* **(g)** *shaded, ordered similarity matrix. (Data simplified from various biochemical and pyrolysis mass spectrometry studies by the author and colleagues.)*

The tree-like structure represents fusions of strains or groups, stretching from the multiple tips, each representing a single strain, to the root, a single line representing the fusion of all strains into a single group. Each branch point in the dendrogram represents the formation of a group with the level of intragroup similarity indicated by the position of the join relative to the axis. Where the join is between two single strains, the similarity of the strains is represented without distortion, but fusions between groups of strains become successively less representative of similarities between individual strains in the groups. In the unweighted pair-group method with arithmetic averages (commonly termed UPGMA) (Sneath and Sokal 1973), the most common method for constructing these figures, the mean group properties are compared at these group fusions. The groups formed at low levels of similarity may contain such diverse organisms that the mean group properties have little relevance to the properties of individual members.

Rooted and unrooted trees (Figure 4b) are essentially dendrograms that radiate from a central fusion out to radial tips representing individual strains. In this case the distance from the tip to a group fusion point represents the level of dissimilarity between the strain and the group mean. Often, each fusion point is annotated with a number showing the number (or proportion) of independent 'bootstrap' analyses that produced a similar fusion, indicating the degree of certainty that the fusion reflects a clear discontinuity in the original data.

Ordination diagrams represent interstrain dissimilarity as a distance. In Figure 4c, each strain is represented as a point, and the distance between pairs of points indicates the dissimilarity between the appropriate strains. However, the distance structure is only partially represented, and clusters of points may contain individual strains or small groups that are distant from the main cluster. This is illustrated in Figure 4d, where the data for Figure 4c are replotted on three axes, showing that group A1 is clearly resolved when a larger proportion of the distance structure is represented. The full distance structure from a large taxonomic study cannot usually be represented on fewer than eight axes.

Ordinations represent the distances between major groups well, but distances for some smaller groups and between individual strains are often represented poorly. This is the converse of tree representations, and comparison of the two types of diagram can highlight defects in the representations. The axes of ordination diagrams are usually complex statistically derived functions termed canonical discriminant variates or principal components. For the mathematically inclined, Manly (1994) gives an excellent explanation of these functions. For those averse to mathematics, each function is a composite measure of many properties that collectively distinguish between groups. These are similar to intuitively derived composite measures that are used in descriptions of stature – ectomorphic, mesomorphic, or endomorphic – where the relative measurements of a complex set of features, rather than any single measurable feature, divide the groups. Composite measures are a common feature of languages; 'fair' complexion describes a composite of pigmentation features and 'gangly' describes a combined measure of limb length, posture, and 'slimness,' itself a composite measure.

Similarity matrices and shaded, ordered similarity matrices are shown in Figures 4e and f, respectively. These represent the interstrain similarities as numbers or graded shading in a tabular form, similar to the tables of intercity distances that can be found in road-map atlases. The shaded tables are particularly useful in highlighting intermingling at the edges of clusters and intergroup similarities that may not be apparent in the topology of a dendrogram. It should be noted, however, that the order of strains markedly influences the clarity of these matrices.

These diagrammatic representations all face the fundamental difficulty that it is usually impossible to fully represent the distance structure determined in a taxonomic study in a two-dimensional diagram. Mathematically, it can be shown that if n strains are examined in t discriminatory tests and $n<t$, then the distance structure may require up to $n-1$ dimensions for accurate representation and can be fully represented only rarely in $< (n-1)^{1/2}$ dimensions. For a taxonomic study involving about 100 strains, this would mean that the data would be fully representable only in ten or more dimensions. Clearly, pictorial two-dimensional representations of similarity data are likely to be deficient or misleading in some aspects. Failure to reveal differences may occur when clusters overlap in ordinations because the axes on which they separate are not plotted, or when isolates 'chain' into unsuitable groups in dendrograms.

THE 'TYPE' CONCEPT AND SERVICE CULTURE COLLECTIONS

The type concept originated from botany, where a single typical dead specimen can supply a wealth of morphological data sufficient to describe the species and to identify further examples. Sneath (1995) has suggested that, with modern characterization methods, preserved dead bacterial specimens might eventually prove equally useful. However, for more than a century bacteriologists have preserved cultures of bacteria as viable organisms. Private collections exist in most departments, but the national service collections, which supply preserved viable cultures, are the prime sources of reference and type cultures. Each valid culturable species has a type culture, which Buchanan (1955) considered to be the reference point for the species.

These service collections are of paramount importance to bacteriology. They provide reference cultures

for comparative identification, quality control of characterization tests, teaching, and taxonomic studies. They often also provide focal expertise in taxonomy and identification and an essential service for identification of the more unusual organisms isolated in routine laboratories. Individual routine laboratories have insufficient time and see insufficient material to register rare, unrecognized pathogens as anything other than unusual. The long-standing high throughput of 'unusual' isolates for identification at national centers has repeatedly allowed identification of previously unnamed groups of bacterial pathogens as new species.

The Centers for Disease Control (CDC) laboratories in Atlanta have a notable record for the detection of such groups, recognized in the genus epithet *Cedecea*. It is particularly important that routine laboratories continue to send unusual isolates to such units, along with definitive information on their source and pathogenic effects, despite budgetary constraints. Equally, these units must continue to provide the identification service and maintain and review their collections of unnamed strains if we are to monitor new and rare pathogens adequately.

However, there are problems with these type and reference cultures. Live cultures maintained by serial subculture inevitably undergo selection and adaptation. Experimental evidence in chemostat (Helling et al. 1987) and batch culture (Atwood et al. 1951) strongly suggest that pure cultures undergo virtually complete clonal replacement with mutated variants after about every 100 divisions. Many older type strains were maintained by serial culture in early collections, and it is likely that most collection strains have undergone multiple predeposition culture cycles. Equally, the methods used to avoid continued subculture, freeze-drying and freezing in cryoprotectants, are highly selective. It is rare to recover more than 1 percent of the initial population from these preserved specimens, and such high kill rates must exert some selective pressure. This selection may be particularly severe for obligate anaerobes exposed to air during subculture. Early microbiologists recognized that biological variation was an inescapable consequence of the culture and storage of strains (Rahn 1929) and used the effect in attenuation of the pathogenicity of anthrax and tubercle bacilli. Modern microbiologists would do well to remember their conclusions.

Equally, reference cultures must be treated with the utmost care outside central collections. There have been several incidents of mislabeled reference strains being passed between research laboratories, with consequent errors in published work, notably with *Candida albicans* (Mackenzie and Odds 1991). All reference cultures should be obtained directly from a recognized culture collection and replaced regularly from the same source.

THE SPECIES CONCEPT

The definition of the species concept in bacteriology continues to be a favorite topic of debate, where those of a philosophical bent can argue free from the constraint of experimental data. A criticism is of the lack of enterprise in obtaining data that might elucidate a solution, rather than of the discussion of this central problem in classification.

In general biology, the best known species definition is that of a sexual interbreeding capability with production of offspring capable of further interbreeding. This definition clearly is not applicable to asexual organisms and is extremely difficult to test in the wild. Indeed, there are many examples where interspecies hybrids are viable, particularly in plants (Eckenwalder 1984) but also in animals (Hall 1978). Clearly, the capability of promiscuous genetic exchange in bacteria invalidates these definitions based on interfertility (Jones 1989). Interspecies exchange of chromosomal DNA has been demonstrated repeatedly (Maynard-Smith et al. 1991), and transposons and promiscuous plasmids can transfer large genetic elements across massive taxonomic gulfs (Natarajan and Oriel 1991; Kirby 1990; Arthur et al. 1987). Other species definitions of more general applicability exist (Simpson 1961; Hutchinson 1965; Van Valen 1976; Templeton 1989) but are not helpful in practical delineation of species.

In practice, identification and most classification work in general biology still relies almost exclusively on comparison of phenotypic characters. The various fine shadings of sexual species definitions are discussed with vigor, but their impact on practical aspects is small. Bacteriologists are probably further advanced on the species concept, with reasonable consensus agreement on a practically applicable, though arbitrary, definition based on DNA hybridization (Wayne et al. 1987). Cohan (2002) reviews species definitions and presents an interesting new definition for bacterial species based on the ecospecies concept.

However, even this consensus has been confused by the adoption of a series of terms that fragment the species concept into variants. Ravin (1963) proposed the terms 'genospecies,' encompassing mutually interfertile organisms, 'nomenspecies,' encompassing organisms 'similar' to the type strain, and 'taxospecies,' encompassing groups that share a high proportion of common properties. The term 'genomic species', readily confused with 'genospecies,' encompasses organisms showing high DNA sequence similarity. These concepts have pragmatic merit (Ursing et al. 1995), but they offer a dangerous attraction to an explosive diversification of concepts of convenience, each with its own classification and nomenclature. Medical microbiologists could easily find the concept of a medicospecies, encompassing a classification that they found particularly convenient,

irresistible in the current milieu of rapid nomenclatural change.

The species concept that seems most universally accepted in practice, if not in theoretical discussion, is the taxospecies: a group of organisms that show high similarity in a broad range of characterization approaches and that are delimited from other organisms by an area of character combinations that are rarely found in nature. This definition is implicit in the numerical taxonomic approach and naturally entrains the concept of polyphasic taxonomy. It does not imply any arbitrary breakpoint of similarity in a specific test, but it requires proof of a discontinuity of variation at the species boundary.

Dividing organisms into species is an unavoidable necessity in biology; routine work invariably requires inference of more general properties from a limited number of observed characters. However, the organisms have no knowledge of, nor any obligation to obey, the divisions that we draw. The boundaries between species can often be diffuse, particularly in bacteriology. However, biologists often give the impression that the natural world can be segmented with absolute clarity into the divisions that we desire. Propagation of this erroneous impression in the general population may well encourage the view that humanity itself can be divided with equal clarity, with all the unsavory consequences that ensue. A definition of the species concept that denies the diffuse uncertainty of biological divisions is as undesirable politically as it is scientifically.

SPECIATION AND EVOLUTION

This is a much neglected area of research, but one in which bacteriology could make a considerable contribution to our understanding. In contrast to higher organisms, bacteria reproduce rapidly. It is possible to produce populations comparable with the entire worldwide population of man within a few days in a fermenter of modest size. Further, bacteriologists have evolved sophisticated techniques for detection and selection of variants forming a tiny proportion of a population. This offers the capability of observing evolution in action over short periods and in a level of detail that cannot be approached in macrobiology. It is unfortunate that the potential for useful work in this area has lain fallow for so long. The few studies to date (Atwood et al. 1951; Helling et al. 1987; Lenski and Travisano 1994) have been largely ignored, possibly because they emphasize a level of variability during successive culture cycles that many modern bacteriologists would prefer to ignore.

Equally, bacteriologists have observed evolution in the wild for many years but ignored its implications for evolutionary science. This is particularly true in medical microbiology. The introduction of antibiotics unintentionally produced the largest experiment in evolution ever undertaken by man, but its results have never been analyzed from an evolutionary viewpoint and the period in which a control population could be observed has long passed. What is obvious from this experiment is that bacteria are eminently suited to evolutionary studies. The high selective pressure of antibiotics and the rapid reproduction of bacteria has spawned, for example, at least five distinct successive races of *Staphylococcus aureus* suited to spread in the ecological niche offered by hospitals within 50 years. Fortunately, much material has been stored in culture collections, and this could provide an invaluable resource should sufficient funding and interest become available.

It is singularly unfortunate that the unique combination of the capabilities of bacteriological techniques and the highly selective environments found in hospitals, particularly intensive care units, has not been brought to the attention of evolutionary scientists, population geneticists, and microbial ecologists. The potential for mutual advantage from such a combination of expertise is enormous. However, the beginnings of interest are now obvious in studies of the genetics of evolutionary change in, for example, the acquisition of resistance to penicillin in commensal *Neisseria* spp. (Bowler et al. 1994) and in multilocus sequence typing of methicillin-resistant *S. aureus* (MRSA) (Oliveira et al. 2002) and glycopeptide-resistant enterococci (Woodford 2001). Population geneticists are beginning to study variation in bacteria (Baumberg et al. 1995; Feil and Spratt 2001; Vogel and Frosch 2002), and the impetus provided by the rapidly decreasing effectiveness of antibiotics against hospital-evolved pathogens may lead to funding of such projects.

ORIGINS, EVOLUTION, AND CONTROVERSY

The Earth is thought to have accreted as a planetary body in the solar disk about 5×10^9 years ago and to have cooled to form a solid surface at about 4.2×10^9 years ago. Prokaryotic life appeared less than 0.7×10^9 years later – a remarkably short time, considering that the subsequent appearance of eukaryotes was a further $1.5–2.3\times10^9$ years later. The earliest fossil evidence of life known at present occurs in the Apex chert in Australia (Schopf 1996). Among the diverse microfossils, some appear to be complex, highly evolved organisms that show close similarity in form and diversity to modern blue-green algae, a prokaryote lineage that appears to have originated midway in the bacterial line according to 16S rDNA phylogenies.

These phylogenies postulate three lineages of life (ignoring the viruses, which probably have multiple origins): the Bacteria (including the Cyanobacteria or blue-green algae), the Archaea, and the Eukarya (Woese et al. 1990). The time of origin of the Archaea is controversial (Cavalier-Smith 2002). These are prokar-

yotic organisms similar in morphology to bacteria but differing markedly in many other aspects. No archaeal microfossils have been found that can be unequivocally distinguished from bacteria by current techniques. The various 16S rDNA phyogenies often place the Archaea as diverging early from the bacterial lineage. However, from evidence of cell and biochemical organization, Cavalier-Smith (2002) argues that the Archaea originated later, possibly as late as the Eukarya.

The first unequivocal fossil evidence of eukaryotes occurs in rock about 1.2×10^9 years old, with less convincing evidence back to 1.8×10^9 years (Lipps 1993). The eukaryotic life forms diversified to give various unicellular lineages, the fungi, plants, and animals, with the first fossil evidence of multicellular eukaryotes occurring about 0.9×10^9 years ago. The Eukarya appear to have acquired prokaryotic symbionts early. There is strong evidence that the mitochondria present in most eukaryotes and the chloroplasts in photosynthetic eukaryotes are symbiotic prokaryotic organisms, descended from, respectively, gram-negative bacteria of the alpha-Proteobacteria line and Cyanobacteria (Margulis and Fester 1991). It is interesting to reflect that the dominant bacterium of the human flora is the mitochondrion, an obligate intracellular symbiont that is present in every cell, is essential to life, and represents a cooperative partnership 1 000 000 000 years old. Nature is not controlled solely by tooth and nail competition. Those who propagate the contrary view to politicians and the public should consider the long-standing symbiosis of mitochondria or chloroplasts, or study the wonderfully intricate symbiotic associations between prokaryotes and eukaryotes reviewed by Fenchel (1996) and Douglas (1996).

Beyond this broad picture of evolution of the three divisions of life, there is beginning to be controversy about the linear branching phylogenies that have dominated past thinking on evolution (Doolittle 1999; Jain et al. 2002; Gupta and Griffiths 2002). An increasing number of papers present evidence that widely divergent groups have exchanged genetic material coding for complex biochemical systems (Andersson and Roger 2002; Ragan and Charlebois 2002; Katz 2002). The evidence suggests that significant lateral genetic exchange between the most widely distinct evolutionary branches of life has occurred, possibly on many occasions. This implies that lateral exchange may be a common phenomenon in closely related lines, where similarities in exchange mechanisms and genome composition favor genetic exchange. There is strong evidence from the genetics of antibacterial resistance that sharing of genetic resources across widely divergent lines is a key option for evolutionary adaptation to adverse conditions. The current linear-branching model for evolution covertly assumes that competitive diversification is the sole mechanism involved. As cooperative redistribution of genes becomes recognized as an important additional mechanism, 'tree-of-life' representations of evolution may be replaced by a reentrant ragged 'web-of-life' model. This type of model is likely to gain early favor among bacteriologists, where promiscuous genetic exchange mechanisms are already well documented, and rapid evolutionary processes, such as acquisition of antibacterial resistance, demonstrate the true complexity of evolutionary mechanisms.

Current views of evolutionary hierarchy for the bacterial lineage are based on 16S rDNA sequencing, which divides the following groups (only genera with members potentially pathogenic to man are named; 'others' indicates nonpathogenic genera not normally encountered in medical microbiology; the order of groups reflects order of branching where possible):

Thermotoga group – others
Bacteroides group – *Bacteroides*, *Prevotella*, *Flavobacterium*, *Cytophaga*, *Capnocytophaga*
High G+C gram +ves – *Mycobacterium*, *Nocardia*, *Streptomyces*, *Corynebacterium*, *Propionibacterium*, *Bifidobacterium*, *Gardnerella*, *Arthrobacter*, *Micrococcus*
Fusobacterium group – *Fusobacterium*
Low G+C gram +ves – *Mycoplasm*, *Ureaplasma*, *Acholeplasma*, *Streptococcus*, *Enterococcus*, *Lactobacillus*, *Listeria*, *Staphylococcus*, *Bacillus*, *Peptostreptococcus*, *Eubacterium*, *Clostridium*
Proteobacteria groups:
Gamma group – *Chromatium*, *Francisella*, *Xanthomonas*, *Coxiella*, *Legionella*, *Pseudomonas*, *Acinetobacter*, *Moraxella*, *Vibrio*, *Aeromonas*, *Haemophilus*, the Enterobacteriaceae + others
Beta group – *Burholderia*, *Alcaligenes*, *Bordetella*, *Neisseria*, *Eikenella* + others
Alpha group – *Wolbachia*, *Rickettsia*, *Brucella* + others + eukaryote mitochondria
Delta group – others
Eta group – *Campylobacter*, *Helicobacter*, *Wolinella* + others
Spirochaetes – *Treponema* + others
Fibrobacter – others
Green sulfur bacteria – others
Planctomyces – *Chlamydia* + others
Cyanobacteria – the blue-green algae + eukaryote chloroplasts

WHAT'S IN A NEW NAME?

Extrapolation of current trends is notoriously unreliable in science, but it is likely that bacterial taxonomy will have to cope with a major increase in the rate of description of new taxa. The background trend is already well established and may well be magnified by new influences. Automated acquisition of characterization data is becoming well established for an ever-wider range of characterization approaches, speeding experimental work, and changing the emphasis of problem-solving effort to data-handling. The international agreements on biodiversity may well increase funding for

taxonomic studies, hitherto poorly funded by industry and public sources. The prospect that species may be patented will clearly lead to increased discovery efforts and provide a financial incentive to the 'splitter' faction. Pending patents have already caused difficulties in the deposition of type strains of commercial significance (Labeda et al. 1995). New technology may well redouble productivity from the molecular biology faction, and DNA sequencing studies of natural environments have already revealed an astounding diversity of previously undescribed and currently nonculturable bacteria, outnumbering described species (Derakshani et al. 2001; Eilers et al. 2000; Paster et al. 2001; Smit et al. 2001).

However, the speed of change in nomenclature has become a problem in applied bacteriology: those who deal with cystic fibrosis patients are, hopefully, aware of the multiple changes in the nomenclature of two major pseudomonad pathogens in the recent past (Hugh 1981; Swings et al. 1983; Yabuuchi et al. 1992; Palleroni and Bradbury 1993). Changes in nomenclature of pathogens generate considerable criticism among medical microbiologists. They are not merely inconvenient; they also increase the problems of communication and may well have unforseen implications in the complex legislation that touches on microbiology in each of the various countries of the world. A further increase in the rate of change could generate a major rift between those who use and those who produce classifications (Magee 1993a).

Key issues for clarification are the date from which proposed changes in nomenclature are to be regarded as active, in the sense that legal proceedings might judge a microbiologist to have erred by using an older nomenclature, and the process of consensus acceptance of change. Most taxonomists and many users regard the date of publication in the IJSB/IJSEM as the date of active change, but many may postpone judgment until the first date of inclusion in an edition of *Bergey's manual*. The latter includes sufficient time to judge the consensus acceptability of the change; the former clearly does not. However, neither solution seems completely acceptable, even at the present rate of change in nomenclature.

If changes in nomenclature are active from their appearance in the IJSEM, then each change is governed by a group comprising the authors of the paper, an editor, and a few referees. Is the judgment of so small a group invariably so reliable, and their insight into the ramifying consequences so broad, that the general community of microbiologists will find the change acceptable? Notwithstanding respect for fellow microbiologists, it is of concern that any group this small can institute changes that may have considerable legal and other consequences on the whole of bacteriology, and that these changes become active, without prior notice, on publication in a journal taken by a minority of applied bacteriologists.

Equally, if active change coincides with mention in *Bergey's manual*, then the interval between editions of about 10 years is too long and the number of concurrent changes to be made is too large. Even here, there is no defined mechanism for judging consensus acceptance of change. One or at most a few experts on each major group write on their subject. There is no guarantee that their interests are so all-inclusive that some change crucial to one branch of the applied science is missed or that their own biases reflect a consensus view of bacteriologists.

The ICSB has a pivotal role in guiding developments in bacterial systematics, including nomenclature, and its members face a new century that is likely to tax their powers of mediation. Negotiating satisfactory compromise between the wishes of applied microbiologists and taxonomists, two groups with widely differing views and requirements, could well require considerable diplomacy. However, the alternative to compromise and cooperation between taxonomists and users is to discard our only internationally accepted scheme of bacterial nomenclature, and this is clearly unacceptable. The solutions to these problems cannot be coercive; the nomenclatural code does not and cannot dictate the nomenclature used by individuals. The wisdom of preserving general acceptance of the formal nomenclature must be convincingly explained to a silent majority, who would much prefer to remain with the nomenclature they were taught years before.

Many of these communication problems could be solved by computerized communication of changes and opinions on the world wide web. One major advance is the availability of lists of all validated names on the world wide web (www.bdt.org.br/cgi-bin/bdtnet/bacterianame). A list of all validated bacterial names of human and veterinary importance is maintained by J.P. Euzéby at www.bacterio.cict.fr/. This site is particularly well maintained and user-friendly and is an essential reference for current names and other taxonomic information. In the interim, efforts are being made to disseminate notification of proposed changes more widely (Frederiksen and Ursing 1995a, b), and this should be supported and encouraged by the community of applied bacteriologists.

An associated problem is the growing gap between the characterization methods used by taxonomists and those available for identification in the routine laboratory. Base ratio determinations, DNA-DNA hybridization, 16S rRNA sequence determination, and chemotaxonomic methods are available in only a minority of routine laboratories and are, as yet, too specialized, tortuous, and slow to have major relevance to identification in routine bacteriology. However, an increasing number of taxonomic papers neglect any mention of characters that can be determined in routine laboratories. The bench microbiologist whose skills lie in identification from colony morphology, pure culture, and

biochemical tests could be excused for regarding this change with horror. This generates a backlash, with regularly heard detrimental comments on the probable capabilities of taxonomists to perform conventional tests, or to examine plate cultures adequately. Clearly, this is an area where medical microbiological input to the formulation of minimal standards for description of new species is essential to our interests. Taxonomists and applied microbiologists must seek mixes of characterization methods that fulfill the requirements of both research and routine work, and revise these as technology advances.

However, medical microbiologists must recognize that they live in a time of great change in bacterial taxonomy. As in all science, taxonomic truth is approached by successive revision in the light of new facts, and the current turmoil in nomenclature is a reflection of growing interest in a subject that forms the basis of routine laboratory work. Nomenclatural change is inevitable and cannot be ignored. Many of the changes may increase the capability to predict important properties from identification results. However, applied microbiologists must also ensure that, when the changes cause problems, these are voiced to the ICSB with sufficiently convincing force, clarity, and representation. The widespread tradition of ignoring nomenclatural change, and restricting critical comment to colleagues in the same field is not helpful to either medical microbiology or taxonomy.

THE FUTURE

The future course of bacterial taxonomy is likely to be interesting and turbulent. We are beginning to discard attitudes and assumptions stemming from the late nineteenth century that have shackled progress for the greater part of the twentieth century. The introduction of numerical taxonomy marked the first major break with the early botanical influence, allowing recognition of the true nature of variation within bacterial species and ridding us of the baggage of monothetic groups and invariant diagnostic characters. Characterization tests now allow comparison of features other than the physiological and nutritional interactions with the environment. Together, these have encouraged the beginnings of exploration of the true diversity of bacteria, which may well produce many unforeseen discoveries of economic significance. Molecular methods are beginning to be used to explore diversification in bacteria, and there is now a possibility that the enormous potential of bacteria in the study of evolutionary processes may be recognized. The phylogeny of bacteria, or at least that of the 16S rRNA gene, is now becoming apparent.

However, these changes are bringing a host of problems. Nontaxonomists are increasingly bewildered by sudden changes in nomenclature and the alienation that this produces must be tackled. The tendency of taxonomists to adopt uniformly a single characterization technique, rather than a polyphasic approach, must be actively discouraged, for it will certainly lead to large, unsupportable swings in nomenclature as techniques fall in and out of style. A major problem of the polyphasic approach is that the full range of characterization techniques cannot be supported in a single laboratory. The consequences of this are that several groups must be involved in each study, and the paper produced must acknowledge a long list of workers in the authorship. The nonscientific problems of contact, cooperation, precedence of discovery, and adequate acknowledgment must be tackled if the polyphasic approach is to become the accepted method of taxonomic advance. Bacterial taxonomy is advancing into the next century in the midst of change. Hopefully, solutions to these problems will be found in a newly matured science that will continue to produce spin-off discoveries of enormous importance in general biology.

ACKNOWLEDGMENTS

My thanks to Professor P.H.A. Sneath and Professor M. Goodfellow for their moderating influence and their many helpful comments on the manuscript.

GROWTH OF BACTERIA

Bacterial nutrition and culture media

A minimal medium is one that contains the simplest chemical composition needed to support the growth of an organism. Some bacteria can grow quite well on a minimal medium consisting of distilled water, a carbon and energy source such as D-glucose, and some inorganic salts, for example sodium and potassium phosphates, ammonium sulfate, magnesium sulfate, and ferrous sulfate. Bacteria able to grow in such a medium must be able gain metabolic energy by the catabolism of glucose and synthesize all organic molecules needed for growth from carbon degradation products of the glucose and the inorganic salts. This carbohydrate–salts medium is chemically defined, in that the exact chemical composition is known and can be reproduced. In stating that such a medium is defined, we ignore the requirement for trace elements such as copper, zinc, cobalt, etc., which are required in only minute amounts and are provided as contaminants in the other ingredients.

If an organism lacks the enzymatic capability to synthesize any organic biosynthetic compounds from such a medium, then growth of that organism cannot occur using that medium unless such compounds are provided. If a mutant of *Escherichia coli* loses the ability to synthesize an amino acid, then that amino acid has become a required growth factor and must be added to the medium or growth of that mutant cannot occur. Many bacteria, especially those whose natural environment contains many complex organic compounds, such as pathogens, are unable to synthesize a wide range of biosynthetic intermediates, such as amino acids, nucleosides, vitamins, etc., and these must be supplied to permit growth. Such a growth medium may be complicated and difficult to assemble, but it is still chemically defined in that the exact chemical composition is known. Because a chemically defined growth medium is reproducible, it is often preferred for studies on the metabolism of bacteria.

Complex and rich bacterial growth media such as those made from nutrient broth (beef extract and peptone) or l-broth (peptone and yeast extract) will support the growth of many bacteria and are convenient to use, but such media are undefined in that the exact chemical composition is not known. Complex and undefined media of these types are often used for isolation and growth of bacteria but it should be realized that the exact composition of such media may vary from batch to batch.

Microbiologists have been ingenious in devising selective media that are designed for the isolation from natural sources of a particular type of microorganism. Such media are designed to facilitate growth of organisms targeted for isolation while discouraging, as far as possible, growth of contaminating organisms. Enrichment

cultures are not only designed to possess the proper media for isolation of a desired organism, but growth conditions such as temperature, can be designed to aid in the isolation. A wide variety of media have also been designed to aid in the rapid isolation and identification of microorganisms, especially pathogens.

Growth in liquid culture

A growing bacterial cell increases in size until it separates into two daughter cells. If growth is balanced and the replication of the macromolecules has been carefully controlled, all of the macromolecules of the mother cell must have doubled in mass and each daughter cell is a duplicate of the mother cell. At that time, a cell generation or division cycle has taken place. The growth of bacterial cells may become temporarily unbalanced as a result of environmental stress, but regulatory systems will normally adjust growth rates so that synthesis of macromolecules once again becomes balanced. Continued unbalanced growth can lead to cell death.

Measurement of cell numbers is often performed by viable cell count. With the pour plate method, various dilutions of cells are mixed into tubes of a melted agar-growth medium that has been cooled to just above the temperature of solidification. The tubes are poured into Petri dishes and, after incubation, the number of colonies is taken as the number of viable cells in the original dilution. An alternate method is the spread plate method, where samples of 0.1 or 0.2 ml of the appropriate cell dilutions are spread over the surface of a solidified agar-growth medium plate. The spread plate method is reported to give slightly higher colony counts and has the advantage that individual colonies can be easily sampled for further testing.

Such information as the viable cell count or number is valuable to many microbiologists, especially those concerned with infectious diseases or food poisoning, because these techniques quantify cells capable of growth. However, such techniques really measure colony-forming units, not necessarily individual cells, as clusters of cells in packets or chains will produce a single colony. Also, it takes many generations of growth for a single cell to produce a colony visible to the unaided human eye. With this technique, a bacterial cell could produce hundreds of thousands of descendants and still be classified as nonviable. A direct cell count measures all of the cells present, including those not capable of growth. It is possible to count the total number of cells per unit volume, both living and dead, microscopically, using a special slide. Cell count as well as mass can also be determined by impedance counting, where cells passing through a narrow chamber disrupt the flow of an electrical current.

A problem with using viable or total cell counts to measure bacterial growth is the inability to detect increases in cell mass during the division cycle. Growing bacterial cells must increase their mass before division and an increase in cell mass must be considered as growth, even though the cell number may not have increased. Cell mass can be determined directly by measurement of cell weight after drying a sample of cells in an oven. Cell mass is often estimated by determining the light scattering of a suspension of bacterial cells with a standard curve to relate light scattering to mass.

The amount of bacterial growth that has taken place in a culture can be estimated by a variety of methods that measure a result of growth rather than cell number. The disappearance of a substrate such as glucose can be determined, or the utilization of oxygen during respiration. A product of growth such as cell deoxyribonucleic acid (DNA), ribonucleic acid (RNA), or protein can be determined, or the amount of acid produced during fermentation might be used as an estimate of cell growth.

The time for a division cycle to be completed is the time for a generation of growth to take place and is known as the generation time. If growth of a bacterial culture is synchronized, all cells are in exactly the same phase of the division cycle, and all will divide simultaneously. With synchronized cell division, the total cell number immediately increases from the initial number (N_0) to $2 \times N_0$. If the cells remain synchronized, another generation will simultaneously raise the cell number to $2 \times 2N_0$. Techniques that have been used for synchronizing cell cultures involve the germination of spores, filtration or centrifugation of cells to obtain a constant size cell, and prevention of initiation of DNA replication by amino-acid starvation. Special mutants have also been used, such as those with temperature-sensitive mutations in genes required for initiation of DNA replication, to prevent cell growth at the restrictive temperature. Upon change to permissive temperature, DNA replication in all cells in the culture will begin simultaneously and all cells will enter the same phase of the division cycle. Synchronization of cell growth can be useful in studying cell chemistry at different phases of the division cycle, but synchronization usually lasts for only a few generations.

CELL GENERATIONS AND GROWTH RATES

Because the total cell number doubles each division cycle or generation (g), the number of cells produced by growth (N) will be equal to the original number (N_o) times 2 to the power g. Therefore:

$$N = N_o \times 2^g. \quad (1)$$

Taking the $\log_{10}$ of both sides of the equation:

$$\mathrm{Log}_{10}N = \mathrm{Log}_{10}N_o + 0.301\ g. \quad (2)$$

Then to solve for g the equation becomes:

$$\frac{\text{Log}_{10}N - \text{Log}_{10}N_o}{0.301} = g. \quad (3)$$

An important value that can be determined from these calculations is t, the generation time. Generation time is the time for each generation to occur so it equals the time elapsed (T) per generation (g), or $t = T/g$. The generation time is also the time required for the cell population to double.

The rate of increase of bacterial number (or mass) is exponential because the population doubles with each generation. If the bacteria are growing at a constant rate, then a plot of cell number or mass against time results in an exponential curve, as shown in Figure 1a. The plot of the $\log_{10}$ of bacterial number/mass against time will give a linear relationship, as shown in Figure 1b, provided the cells are growing at a constant rate. This is the conventional method of plotting bacterial growth.

The rate of increase in total cell number during growth is the initial cell number multiplied by the specific growth rate constant (μ):

$$\frac{dN}{dT} = \mu N. \quad (4)$$

The value of the specific growth rate constant can be derived from the plot of log N versus t, where its value will be given by the slope of the linear plot. The specific growth rate constant is not the same as t but represents the growth rate at a specific instant.

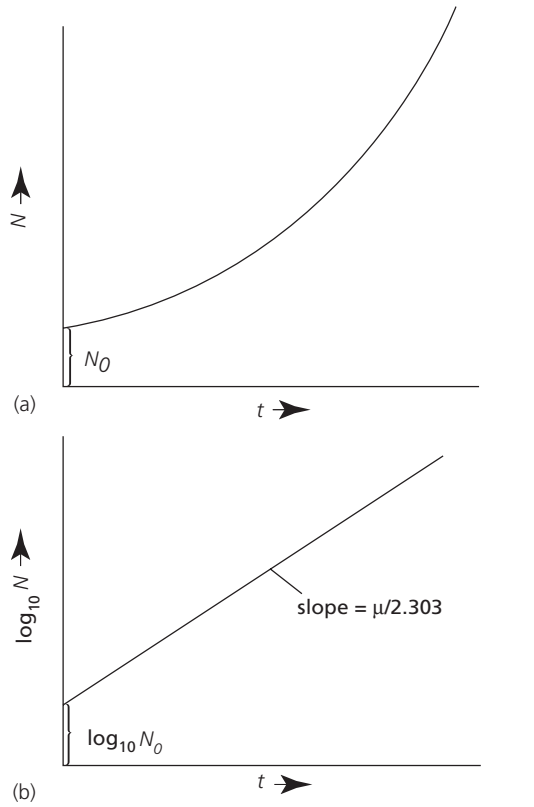

Figure 1 *Theoretical growth curves illustrating instantaneous exponential growth in a bacterial batch culture. Total cell number (*N*, i.e. number of bacterial cells per ml) plotted against time (*t*). N_0, inoculum cell concentration; μ, specific growth rate*

THE GROWTH PHASES AND THE GROWTH CURVE

The lag phase

When an inoculum of cells is transferred to a growth medium, a delay may take place before measurable growth occurs. This lag time is a period where cells are adjusting to new growth conditions, and growth may be temporarily unbalanced during this growth phase. The greater the change in growth conditions, experienced by the cells, the longer the predicted lag phase. Because cells must increase their size before cell division can take place, the exact length of the lag period may depend upon whether cell number or cell mass is being measured. A typical bacterial growth curve, with lag and exponential and stationary phases, is shown in Figure 2.

The exponential (logarithmic) growth phase

Once the cells have adjusted their regulatory systems to producing maximum growth under the new conditions, the culture enters the exponential or logarithmic growth phase where cells have approximately the same generation time. Growth is normally not synchronized and, at any moment, cells will be at different stages of the division cycle. In batch culture the growth rate eventually

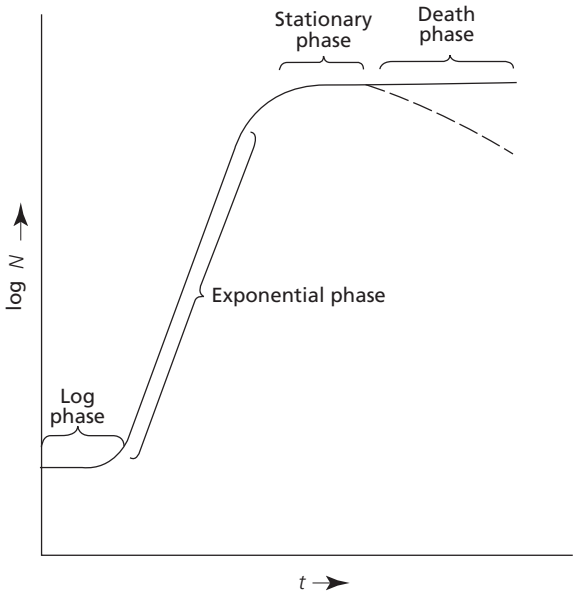

Figure 2 *Idealized growth curve of a bacterial batch culture. Unbroken line, total cell count; dashed line, viable cell count*

must begin to decrease as the availability of some essential nutrient becomes limiting or the accumulation of some product becomes toxic.

The stationary phase

Eventually the stationary phase is reached, a period where measurable growth ceases. Note that if a new viable cell was formed for each cell that lost viability, or if loss and increase in cell mass were balanced, then there would be no measurable increase in cell growth.

If *E. coli* cells are growing on a minimal salts medium containing a carbon and energy source and the energy source becomes exhausted, the pH will remain constant and growth and nitrogen utilization will both stop. However, under conditions where the nitrogen becomes depleted and the energy source is in excess, the cells will continue to use the energy source, even if the energy gained from catabolism is discarded. If possible, the bacteria will increase their internal supply of reserve food material under these conditions, while denying surrounding microorganisms a potential energy source. Traditionally, resting cells of bacteria are those incubated without any added nitrogen source. Such cells are still able to induce enzymes and catabolize carbohydrates, and these types of resting cells have been used for many metabolic studies.

The death phase

Some bacteria retain viability upon reaching the stationary phase, while others rapidly lose viability and enter a death phase. A variety of circumstances, including loss of energy and production of autolytic enzymes, may cause bacteria to lose viability. Reserve food sources that may be accumulated by bacteria, such as poly-β-hydroxybutyric acid and glycogen, are usually used quickly when the cells are starving but once such reserve food materials are exhausted, cellular RNA may serve as its major source of energy. Ribosomal RNA degradation may increase during starvation conditions. For example, *E. coli* can degrade 20–30 percent of its RNA within 4 h of starvation. The degradation of ribosomes will lead to the eventual death of the cell because cells lacking ribosomes are incapable of synthesizing protein. Starvation also increases the rate of protein degradation and peptidase-deficient mutants of *E. coli* have been shown to have poor survival during starvation for carbon and nitrogen. The amino acids produced by protein degradation can be used for the synthesis of new proteins to aid in survival under stress conditions.

A drop in internal energy levels may prevent transport of nutrients across the cytoplasmic membrane so that, upon transfer to recovery medium, the cell is unable to uptake nutrients. The energy charge of a cell has been reported as the total adenosine triphosphate (ATP) plus half of the adenosine diphosphate (ADP) over the totals of the cellular ATP, ADP, and adenosine monophosphate (AMP). Because two ADP are capable of forming one ATP and one AMP, the amount of ATP that can be obtained from ADP is equal to one-half of the ADP present. The equation

$$\text{energy charge} = \frac{\text{ATP} + {}^{1}\!/_{2}\ \text{ADP}}{\text{ATP} + \text{ADP} + \text{AMP}} \qquad (5)$$

gives the ratio of available ATP to the total adenine nucleotides present. If all of these nucleotides were in the form of the triphosphate, the energy charge would be one. For the normal growth and metabolism of bacterial cells, the energy charge must be maintained in the range of 0.80–0.95; *E. coli* has been reported to grow only when the energy charge is over 0.8, it will maintain its viability when the energy charge is between 0.5 and 0.8, but it will die when the value is under 0.5. There is a certain amount of maintenance energy required just for cells to repair continuing damage but this may vary for different organisms. In experiments with *E. coli*, it was found that once the glucose was exhausted the organism maintained its energy charge at 0.8 by using acetate that had been excreted during growth on glucose. If no other substrates were present, then the capacity for protein synthesis and enzyme induction was lost along with cell viability.

Because a starving cell must maintain a certain level of metabolism and energy to remain viable, many bacteria activate special regulatory systems in response to starvation, regulatory systems that allow them to express 'starvation' genes (Matin 1992). These new proteins improve the cell's ability to use low levels of nutrients, regulate the degradation of their own polymers for carbon and energy, and aid the cells in surviving. Many of the genes encoding for these proteins require the nucleotide cyclic AMP for their induction. The starvation stress regulatory system may overlap with other stress regulatory systems because starved *E. coli* cells have been shown to acquire resistance to heat stress.

In *E. coli*, the nucleotide guanine triphosphate has an essential role in the regulatory adjustments made by cells starved for amino acids. This adjustment to amino-acid starvation is known as the stringent response. In cells with insufficient amino acids, the stringent response will cause a rapid reduction in the synthesis of ribosomal and transfer RNA.

CHANGING GROWTH RATES

The rate of growth of a bacterial strain may be shifted up or down with changes in growth conditions, such as medium composition or temperature. Shift-up experiments refer to a change in growth conditions with an increase in the growth rate of a bacterium. As an

example, an improvement in nutrient conditions can lead to an increase in the internal amino acid concentration, thus resulting in an increase in rate of RNA synthesis, an increase in the rate of protein synthesis, and a more frequent initiation of DNA synthesis. Faster-growing cells tend to be larger, with an increase in the amount of the protein-synthesizing machinery. While the regulatory systems are adjusting to the new conditions, the cell length may continue to increase and the cell may become unusually long. Eventually, the cell length decreases to reach the proper size for the new growth rate (Cooper 1991).

By contrast, a transfer of cells from a complex undefined medium, such as a nutrient broth, to a minimal-salts medium can result in a shift-down or decrease in growth rate caused by a sudden decrease in internal concentration of nutrients, such as amino acids. A decrease in the internal concentration of amino acids leads to a stringent response with a decline in the rate of RNA synthesis, a decline in the rate of protein synthesis, and a less frequent initiation of DNA replication. In fact, DNA synthesis may halt altogether, until activation of biosynthetic pathways can produce the required building block compounds to permit cell growth.

Continuous culture of bacterial cells

The chemostat is a name given to devices that maintain the growth of bacteria in a constant exponential growth rate. A typical chemostat possesses a container containing sterile growth medium that is transferred into the growth chamber at a controlled rate. The growth chamber has an overflow device so that the entrance of new medium results in the overflow and exit of an equal volume of used medium, as shown in Figure 3.

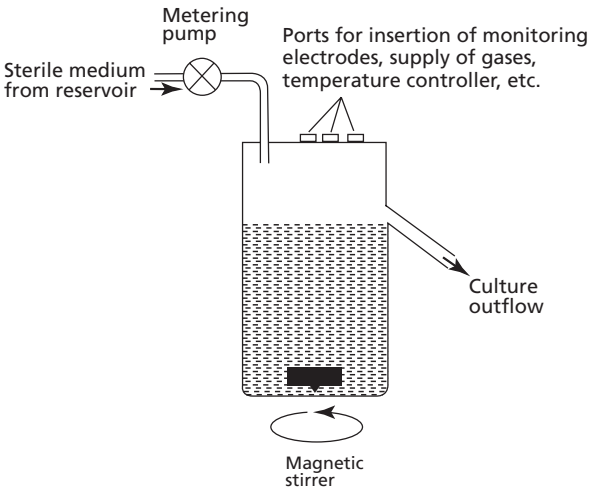

Figure 3 *Principal features of a continuous-flow culture apparatus*

CHEMOSTAT GROWTH RATES

The medium in the growth chamber of a chemostat can be inoculated with a bacterium to give an initial cell concentration of (N). If growth takes place, the rate of increase in cell mass against time can be represented by $dN/dt = \mu N$, where N is the cell number per unit volume and μ stands for the growth rate constant. The rate of increase in cell number can be represented as μN. If the growth rate constant is a positive number, the cell mass in the chemostat will be increasing. However, new medium is introduced into the chemostat at a constant flow rate and old medium is overflowing out of the chemostat at the same rate, removing cells. If the flow rate into the chamber is F volume per unit time period, and the volume of the growth chamber is V, then the fraction of the culture medium that overflows and is replaced each unit time period is represented by F/V (also known as the dilution rate). Therefore, the total amount of cells lost each time period by overflow would be $N \times F/V$. The real rate of change of cell number in the chemostat is the rate of increase resulting from growth (μN) minus the rate of decrease as a result of washout ($N \times F/V$). Therefore, the rate of change in the chemostat is $\mu N - N \times F/V$, or $N(\mu - F/V)$.

If F/V is greater than μ, the cells are being washed out of the chemostat faster than they can grow and eventually all of the cells will leave the chemostat. If F/V is smaller than μ, the number of cells will increase. However, as the cell mass increases, there are more cells competing for a constant food supply, because the flow rate into the growth chamber is constant and this competition causes a decrease in the growth rate constant. Eventually μ will decrease until it equals F/V and then a steady state will exist with μ held constant. In such a manner, by controlling the rate of flow of new medium into the chemostat, the experimenter can control the growth rate of the cells in the chemostat.

Chemostats are usually established with the growth rate limited by a single known factor, such as a limiting supply of a required growth factor or the carbon and energy source. Chemostats are very useful for obtaining mutants, because once a growth rate is established there is strong evolutionary pressure for selection of mutants that have increased their growth rates under the competitive chemostat conditions. However, chemostat experiments must often be terminated because of the selection of 'sticky' mutants that cling to the culture-vessel surface and are not washed out.

CHEMOSTAT CELL POPULATIONS

If the concentration of the limiting nutrient in the reserve chamber is designated as S_r and the unused amount of that nutrient that washes out of the chemostat is S, then the amount of nutrient used by the cells in the growth chamber is $S_r - S$. If Q represents the amount of that limiting nutrient needed to make one bacterial cell, then

the total population of cells will be equal to $S_r/Q - S/Q$. However, S is usually close to zero and then the equation becomes S_r/Q, which represents the total population of cells. The growth rate in the chemostat is controlled by the rate of flow of new medium into the chemostat, but the total population of cells present is determined by the concentration of the limiting substrate.

Growth on solid surfaces

Good growth for a bacterium such as *E. coli*, on rich medium, under aerobic conditions, may range from 1×10^{10} to 5×10^{10} cells per milliliter. The final yield of cells per milliliter in liquid culture can be considerably increased if the cells are placed within a dialysis sack that is suspended in a large vessel of growth medium. The dialysis sack permits waste products to diffuse out of the sack, away from the cells, while fresh nutrients can diffuse into the sac. Cells growing on an agar surface can form colonies with high concentration of cells per unit volume for a similar reason. The agar permits nutrients to diffuse toward the colony, while waste products diffuse away.

The nutritional state of bacteria may also influence their adhesion to solid surfaces. Many bacteria have increased adhesion under starvation conditions but some bacteria actually display the opposite effect. Colonization of surfaces by bacteria may be influenced by motility and cell-surface hydrophobicity as well as by nutritional status (James et al. 1995). In nature, masses of cells commonly exist in films or mats and the cells in such masses may be able to regulate overall behavior by communication systems. Bacteria may grow in a manner that maximize cell-to-cell contact and, perhaps, cellular communication. For this reason, some microbiologists view the bacterial colony as a multicellular 'organism,' an organized population of communicating cells (Shapiro 1995).

STRUCTURE AND ORGANIZATION OF THE BACTERIAL CELL

General composition of bacteria

In order for bacterial cells to grow, they must be provided with all of the chemical elements needed for the synthesis of new cellular material. Once, organisms that could use simple molecules to satisfy their nutritional requirements, such as carbon dioxide (CO_2) as the sole carbon source, were thought of as 'simple' organisms. We now understand that the simpler the nutrients, the more complex the biochemical reactions required by the cell to convert those nutrients into complex cellular material.

The water content of bacterial cells can vary from 75 to 90 percent of the total weight. The dry weight, after removal of water, is composed of about 50 percent carbon, about 10 percent hydrogen, and about 20 percent oxygen. The nitrogen content of the dry weight can vary from 8 to 15 percent, sulfur from 0.1 to 1.0 percent, and phosphorus from 1 to 6 percent. The iron content is also variable and is highest in cells with heme proteins. Other elements found are potassium, calcium, magnesium, chlorine, sodium, zinc, cobalt, molybdenum, manganese, and copper. These and other trace elements total about 0.3 percent of the dry weight.

Cellular polymers

Most of the organic material in the bacterial cell is in the form of large polymers. However, the cell cytoplasm also contains a 'soluble pool' of smaller, unpolymerized organic molecules such as amino acids, nucleotides, carbohydrates, and fatty acids, as well as degradation products from the breakdown of any compounds providing carbon and energy sources for growth. Large organic polymers of the cell include those made of amino acids (proteins), those made of ribonucleotides (RNA), those made of DNA, and those composed of carbohydrates and lipids.

Detailed studies of polymer composition have been carried out in only a few bacteria. In *E. coli* protein represents about 50 percent of the dry weight of a typical bacterial cell. RNA represents about 20 percent of the dry weight of a bacterial cell but can vary depending upon growth conditions. About 90 percent of the RNA is ribosomal RNA (rRNA), which consists of three species, the 23S rRNA, the 16S rRNA, and the 5S rRNA. The transfer RNA (tRNA) represents about 9 percent of the total RNA, with 60 types of tRNA. The messenger RNA (mRNA) represents about 0.2–1 percent of the total RNA. There may be one to four molecules of DNA, depending upon the growth rate, representing about 3.3 percent of the dry weight (Neidhardt 1987). Carbohydrate polymers are present in the cell wall and may also be stored in the cytoplasm as food materials such as glycogen. Lipid material can vary from 1 to 8 percent of the cell dry weight, depending upon growth conditions, and can be found in the cell membrane and wall. Some bacteria, excluding *E. coli*, can store lipid-like substances as reserve food material, often in the form of polyhydroxybutyric acid granules in the cytoplasm. For the synthesis of this storage material, two acetyl-coenzyme A (acetyl-CoA) molecules are converted to acetoacetyl-CoA; this is changed to D-(-)-3-hydroxybutyryl-CoA, which is polymerized to form polyhydroxybutyric acid (Steinbuchel et al. 1991).

Eubacterial cell walls

PEPTIDOGLYCAN MATERIAL

The backbone structure of the eubacterial cell wall is the peptidoglycan material. Peptidoglycan is a polymer of N-acetyl glucosamine and N-acetyl muramic acid, linked together by β-1,4 or 1,6 alternating units and about

12 carbohydrates long. The disaccharide chains are linked together by polypeptide chains, usually from three to eight amino acids long and containing some D-amino acids such as D-alanine and D-glutamic acid. The polypeptide chain is attached by a peptide bond to the carboxyl group of the muramic acid. It normally contains one diamino acid, such as lysine or diaminopimelic acid but not both, and a short peptide bridge joining the free amino group of the diamino acid to the terminal carboxyl group of a similar polypeptide branch from a different disaccharide strand. In such a manner the backbone disaccharide strands are joined together. The cross-links in the peptidoglycan material form a 'web' capable of supporting stress in any direction. During synthesis of the peptidoglycan material, a disaccharide of N-acetylglucosamine and N-acetylmuramic acid is first formed and the amino-acid bridges are then attached with an extra D-alanine on the end of the peptide chain. Teichoic acid and peptide-bridge material may also be added to the unit. To build new wall material, this disaccharide–peptide unit is inserted into the existing cell wall in the space between the cytoplasmic membrane and the cell wall. A membrane-linked transpeptidase removes the final D-alanine unit from one peptide chain or peptide bridge and installs in its place the extra amino group on the diamino acid of another chain. The presence of D-amino acids in the cell wall is believed to give protection to external proteolytic enzymes. Enzymes that attack the bacterial cell wall are termed lysins, and autolysins are lysins, produced by the bacterium itself. Some lysins attack the peptidoglycan backbone, whereas others attack the peptide portion or the point where the peptide chain joins the glycan strands. Lysozyme is a lysin that cleaves at the β-1,4 linkage of N-acetylglucosamine.

GRAM-POSITIVE CELL WALLS

Gram-positive cell walls contain peptidoglycan and may also contain teichoic acid, polymers of glycerol or ribitol, usually about 10 to 50 units long, and linked together through phosphate bonds. Most teichoic acids are covalently linked to the peptidoglycan. Side groups on the teichoic acids can be carbohydrates such as glucose and N-acetylglucosamine and/or amino acids such as D-alanine. Teichuronic acid, a polymer consisting of alternating glucuronic acid and N-acetylgalactosamine, is sometimes found in the cell walls, especially when phosphate is limiting. Lipoteichoic acids are polymers of glycerophosphate covalently linked to a lipid molecule. The bound lipid allows the molecule to be anchored in the lipid bilayer of the cell membrane. However, the glycerophosphate polymer is not linked to the peptidoglycan.

GRAM-NEGATIVE CELL WALLS

The gram-negative cell wall is more complex than that of the gram-positive bacteria. One layer contains peptidoglycan material; the other layer is a convoluted outer membrane consisting of protein and at least two types of lipids: lipopolysaccharides (LPS) and phospholipids. The peptidoglycan material makes up only about 12 percent of the total cell wall material in *E. coli* and the four amino acids usually found in the peptidoglycan material of gram-negative cells are L-alanine, D-glutamic acid, *meso*-diaminopimelic acid, and D-alanine. LPS consists of three parts: an inner hydrophobic lipid A region, an outer hydrophilic O antigen polysaccharide region, and a core polysaccharide region that connects the A and O regions. The phospholipid and LPS form an asymmetric bilayer, with the phospholipid forming the inner layer and LPS forming the outer layer.

Proteins found in this outer wall include murine lipoproteins. The lipid end of this protein is embedded in the inner face of the bilayer formed by lipid and LPS. The protein end can be bound to the peptidoglycan. The main function of murine lipoprotein may be to help stabilize the outer membrane–peptidoglycan complex. Other important proteins found in the outer wall are porins, which form channels to allow the diffusion of hydrophilic molecules. Porins are sometimes grouped into three types (Nikaido 1992). Type 1 are nonspecific porins that distinguish substrates on the basis of size. A zone of constriction arising from the folding of a stretch of residues into the central pore allows porins to distinguish substrates on the basis of size (Cowan et al. 1992). Examples of this type are OmpF and OmpC of *E. coli*. Type 2 porins are related to type 1; both only permit diffusion of small substrates, but the type 2 porins preferentially transport certain substrates. The LamB porin of *E. coli*, which preferentially transports maltose and maltodextrins, is representative of this type of porin (Schirmer et al. 1995). LamB is also the binding site of the lambda phage. The third types of porins are TonB-dependent porins. TonB-dependent porins specifically transport certain substrates such as vitamin B_{12} or siderophores. These porins are unique in that transport is energy dependent. The energy is supplied through the TonB protein, which resides in both the cytoplasmic membrane and the outer cell wall (Moeck and Coulton 1998).

Between the outer and cytoplasmic membrane of gram-negative organisms is the periplasmic space, which contains many proteins, including transport-binding proteins, scavenging enzymes, detoxifying enzymes, and others. Periplasmic enzymes are synthesized in the cytoplasm and must be transported across the cytoplasmic membrane. Many periplasmic proteins contain a signal sequence of about 20–40 amino acid residues long at their N-terminus (Pugsley 1993). This sequence contains a positive region followed by a hydrophobic region and terminates in a peptidase cleavage site. The signal sequence targets the protein for transport via the Sec transport system (also known as the general secretory pathway). Once transport is completed, the signal sequence is cleaved from the transported protein.

A Sec-independent system for export of periplasmic proteins has been identified in *E. coli* (Weiner et al. 1998). This system recognizes proteins with a 'twin-arginine' motif at their N-termini. Proteins transported by this system appear to be mainly redox proteins containing cofactors. Related proteins are found in a wide range of bacteria, suggesting that this is an important transport system for periplasmic proteins.

Archaea cell walls

The third domain of life, the archaea, have distinctively different cell-wall polymers from the eubacteria (Kandler and Konig 1998). They do not possess the peptidoglycan polymer but may possess a slightly different polymer termed pseudopeptidoglycan. In the genus *Methanobacterium thermoautotrophicum*, this polymer contains N-acetyltalosaminuronic acid and N-acetylglucosamine and only L-amino acids, such as L-lysine, L-alanine, and L-glutamate. The cell wall of *M. ruminantium* has L-threonine in place of L-alanine, and N-acetylgalactosamine in place of N-acetylglucosamine. The synthesis of this polymer is unique to bacteria containing pseudopeptidoglycan. The cell walls in the genus *Methanosarcinaceae* are made of an acid heteropolysaccharide that contains galactosamine, neutral sugars, and uronic acids. No muramic acid, glucosamine, glutamic acid, or other amino acids typical of peptidoglycan are found. Most archaea also contain an S-layer (see below) as a cell envelope. Because the cell walls of archaea are structurally distinct from eubacterial walls, almost all of the antibiotics that target synthesis of components of the wall in eubacteria are ineffective against archaea; for example, β-lactam antibiotics and vancomycin do not inhibit growth of archaea.

Polymers external to the cell wall

Capsule or slime layers may exist as polymers outside the cell wall. They are usually made up of amino acids, carbohydrates, or both; for example, the polypeptide capsule of *Bacillus anthracis* is mostly D-glutamic acid, whereas the *E. coli* K-12 capsule consists of D-glucose, L-fucose, galactose, hexuronic acid, acetate, and pyruvate. Often the extracellular material is not tightly linked to the cell wall. Such loosely adhering material is referred to as a slime capsule. In pathogens surface polysaccharides are an important surface antigen. In *E. coli* the surface polysaccharide gives rise to the K antigens, of which there are more than 80 serotypes (Whitfield and Roberts 1999). Capsules are also important virulence factors. The capsule of *B. anthracis* is critical for cell survival during infection. Strong bonding forces rarely link capsule polymers to one another, although highly acidic types can be cross-linked by divergent metals such as Mg^{2+} or Ca^{2+}.

Another extracellular assemblage is known as the S-layer. The S-layers are made up of protein subunits that are sometimes glycosylated (Sleytr and Beveridge 1999). The unique feature of S-layers is that the subunits spontaneously form higher-order structures with crystalline lattices. S-layers are found in both eubacteria and archaea.

External appendages

Many bacteria contain appendages that extend beyond the outer cell wall. One of these is the bacterial flagellum. Flagella are used to propel bacteria in directions favorable for survival and growth. The flagellar structure can be broken down into three basic units, termed the basal body, the hook, and the filament (Manson et al. 1998). The basal body anchors the flagellum into the cytoplasmic membrane and contains numerous proteins required for assembly and function. The hook is a short curved region that links the basal body to the filament. Attached to the hook is a helical filament made up primarily of a single protein termed flagellin. The filament rotation which propels the cell forward, is driven by the ion gradient across the cytoplasmic membrane. Because the filament is helically shaped its rotation can propel the cell.

Flagella do not just randomly propel the cell through its environment. Cells have external receptors that detect environmental stimuli and then, using a phosphorelay system, this information modulates rotation of the flagellum. In *E. coli* counterclockwise rotation of the flagella produces forward movement termed 'runs,' while clockwise rotation causes cellular 'tumbling.' Stimuli that prolong runs are called attractants and stimuli that shorten the length of a swimming interval are called repellents. Changes in attractant or repellent levels cause changes in flagella rotation and result in movement in favorable directions. Other bacteria, for example *Rhodobacter sphaeroides*, can rotate their flagella in only one direction (Armitage and Macnab 1987). So, instead of runs and tumbles *R. sphaeroides* cells run and then stop and randomly re-orient. There are similarities in the signaling pathways in *E. coli* and *R. sphaeroides*, but the two pathways are not identical.

Many bacteria also possess external protein fibers known as pili or fimbriae composed of protein (pilin). The pili of pathogenic bacteria contain specific proteins that allow the bacteria to attach to and colonize host tissues. Binding of pili to external surfaces may be a key factor in activating expression of genes required for infection in pathogenic *E. coli* (Zhang and Normark 1996). There are other types of pili, referred to as sex pili, that are used by bacteria to attach to each other and exchange DNA.

Cytoplasmic membrane

The cytoplasmic membrane is made up of both lipid and protein and can constitute about 10 percent of the dry

weight of the bacterial cell. In most cases the lipid is primarily phospholipid. The fatty-acid components of the phospholipid can be varied to maintain the appropriate fluidity of the membrane. Cyclopropane fatty acid is also a common modification of the lipids of the cytoplasmic membrane. It has been demonstrated that increases in content of cycloporane fatty acids render cells of *E. coli* more sensitive to acidic pH (Chang and Cronan 1999).

At least 200 different kinds of protein representing up to 6 to 9 percent of all the cellular proteins are located in the cytoplasmic membrane. Some of these proteins are cytochromes, dehydrogenases, NADH-oxidases, enzymes involved in cell-wall synthesis, enzymes involved in electron transport and oxidative phosphorylation, and proteins involved in the transport of specific molecules through the membrane. Typically, membrane-associated proteins are divided into two classes, integral and peripheral membrane proteins. Peripheral proteins associate with the surface of the membrane through ionic interactions. Therefore, they can be removed by treatment of the membrane with high concentrations of salt. Integral proteins are embedded in the lipid bilayer and can be dissociated from the bilayer only by the use of detergents. Integral proteins must contain surface-exposed hydrophobic regions to interact with the hydrophobic regions of the bilayer. In many cases these hydrophobic regions form α-helices and are termed membrane-spanning helices. In *E. coli* integral membrane proteins are targeted to the membrane by the signal recognition particle and the protein FtsY (Ulbrandt et al. 1997). Proteins to be translocated across the membrane by the Sec system are targeted by the SecB protein, differentiating the transport pathways of these two classes of proteins.

The cell membranes of archaea chemically differ from eubacterial membranes. The membrane lipids of archaea are isopranoid alcohols, typically 20 or 40 carbons long, and ether-linked to glycerol. The C20 alcohols can be linked together giving rise to the C40 molecules. The glycerol groups can be modified with a number of different polar head groups. It has been suggested that the use of the novel lipids by Archaea allows them to tolerate extreme environments better (van de Vossenberg et al. 1998).

The cytoplasm

A typical bacterial cell is able to synthesize over 1000 different enzymes to catalyze the many chemical reactions needed for cell growth. Catabolic pathways provide the cell with the energy for growth, while anabolic reactions are the biosynthetic reactions whose purpose is the formation of new cellular material. Although a bacterial cell may possess the ability to synthesize over 1000 different enzymes, its regulatory systems are evolved to control the synthesis of such proteins, and the exact type and quantity of enzyme may be carefully regulated.

Enzymes function as catalysts and rapidly cause the equilibrium of thermodynamically feasible chemical reactions to be reached. Although an enzyme must participate in the reaction it catalyzes, binding substrates and releasing products, it is normally regenerated and can be reused when the reaction is completed. The activity of many enzymes is associated with a relatively low-molecular-weight compound termed a coenzyme (or prosthetic group or cofactor). The catalytic site of the enzyme binds the substrate and the enzyme–substrate complex changes to an enzyme–product complex with the release of the product. The specificity of enzyme action results from the specific recognition of the substrate by the catalytic site. Many enzymes will act upon compounds related in chemical structure to the natural substrate but usually with lower binding affinities. Sometimes such compounds are converted to products and released but some can bind to the enzyme and block activity. Enzyme activity can also be destroyed or inhibited by a variety of chemicals or conditions, including those that alter the structure of proteins in a nonspecific manner.

As increasing concentrations of a substrate are presented to an enzyme, the velocity of the enzyme-catalyzed reaction will increase until, at substrate concentrations sufficient to saturate the available catalytic sites, the rate of reaction will be sustained at some maximum value (V_{max}). Thus, a plot of reaction rate (v) versus substrate concentration [S] frequently approximates to a rectangular hyperbola. An enzyme displaying these kinetic properties is said to demonstrate Michaelis–Menten kinetics and the relationship between the reaction rate and substrate concentration can be described by the maximum velocity (V_{max}) constant and the Michaelis constant (K_m), which is the substrate concentration that limits the rate of the enzyme-catalyzed reaction to be one-half that of V_{max}. Studies of how V_{max} and K_m change under different chemical and physical conditions can provide information on the nature of the substrate–enzyme complex.

The regulatory mechanisms of bacterial metabolism are designed to permit a controlled synthesis of cellular polymers, usually as rapid as possible under the existing environmental conditions. Bacterial cells are not simply a 'bag of enzymes', as was once suggested. Indeed, there is careful organization of many proteins within the bacterial cell. Multienzyme complexes can be found within the cytoplasm and many enzymes and transport proteins are incorporated in the cell membrane or, in the case of gram-negative bacteria, within the periplasmic space. Some proteins involved in anabolic processes themselves are regulated. These allosteric proteins possess a site for binding a low-molecular-weight molecule termed an effector. The effector molecule may

be quite different from the substrate molecule, but its binding to the enzyme results in a conformational change at the active site with a change in the affinity of the active site for the normal enzyme substrate. A positive effector will increase the binding capability of the enzyme for its substrate, while a negative effector will decrease the binding capability. With normal intercellular substrate concentrations, a positive effector will increase the rate of reaction, while a negative effector will decrease the rate of reaction. Proteins with nucleic acid binding sites can also have their binding ability increased or decreased by effector molecules.

BIOSYNTHESIS OF DNA, RNA, AND PROTEIN

The bacterial chromosome and DNA replication

The DNA of the chromosome in a typical bacterial cell can be 500–1 000 times as long as the cell itself. This molecule is compacted by folding and supercoiling. The initiation of chromosomal replication requires a certain cell mass before replication can begin. Replication of the chromosome proceeds bidirectionally from the origin of replication (in *E. coli* this is termed *oriC*). Replication requires that the DNA strands become unwound, forming an open complex. In *E. coli* formation of the open complex requires the protein DnaA and a few other proteins. DNA polymerases then synthesize DNA in the 5′–3′ direction using a 3′-hydroxyl primer. *E. coli* has three DNA polymerases, two of which are required for replication of the chromosome. Polymerase III replicates the chromosomal DNA. Because DNA polymerase III needs a primer to begin DNA polymerization on a single-stranded template, a polymerase is needed first to form an RNA primer. After DNA polymerase has used these primers for the elongation of the DNA, they are replaced by DNA. In the 3′–5′ direction, RNA primers are formed and, after the formation of 1 000- to 2 000-long DNA strands termed Okazaki fragments, destroyed and replaced by DNA using DNA polymerase I. The nicks between the Okazaki fragments are repaired by DNA ligase (Bremer and Churchward 1991). Because replication is bidirectional, the two replication regions (termed replication forks) meet at a region in the chromosome called the termination region. This region blocks progression of the replication forks and allows termination to occur.

Some strains of bacteria have been reported to have more than one chromosome; for example, a strain of *R. sphaeroides* (strain 2.4.1) has been reported to contain two circular chromosomes as well as five plasmids (Suwanto and Kaplan 1989). The two chromosomes are 3.0 million base pairs (Mbp) and 0.9 Mbp in size. Another bacterium with multiple chromosomes is *Deinococcus radiodurans* (Lin et al. 1999). Interestingly this bacterium also contains multiple copies of each chromosome (Hansen 1978). This polyploidy has been suggested to play a role in the radiation-resistance of this bacterium. However, there are probably other factors involved because other bacteria, such as *Azotobacter* (Punita et al. 1989), are polyploid but are sensitive to ionizing radiation.

Protein synthesis

While the DNA contains the sequence information for the various proteins of the cell, the RNA is the machinery that translates that information into the polypeptide chains. The genetic code is triplet, meaning that three nucleotides determine the code ‘word’ for each amino acid. Because there are four nucleotide ‘letters’ (A, T, G, and C in the DNA alphabet and A, U, G, and C in the RNA alphabet), it is possible to have 64 different ‘words’ or codons for the 20 amino acids normally found in proteins. The genetic code is also degenerate in that there may be more than one codon for any one amino acid but no nucleotide triplet will code for more than one amino acid; for example, there are four mRNA codons for serine, UCU, UCC, UCA, and UCG. It has been speculated that the code was once a doublet rather than a triplet and, therefore, the original doublet code for serine might have been UC. Three codons called nonsense codons usually do not code for any amino acid and signal when to end synthesis of a polypeptide chain.

Amino acids are activated before being added to a polypeptide chain by being placed on specific tRNA molecules. An enzyme specific for each amino acid (aminoacyl tRNA synthetase) transfers the amino acid to the tRNA specific for the transfer of that amino acid. These tRNA molecules are about 80 nucleotides in length and each has a site recognized by its tRNA synthetase. The amino acid is first activated using ATP, resulting in the formation of an aminoacyl–AMP complex. This complex is transferred to the tRNA molecule and the tRNA molecule is said to be ‘charged.’ In such a manner, each tRNA can become ‘charged’ at its amino-acid attachment sites with the proper amino acid. The tRNA also possesses a ribosomal recognition site as well as a codon recognition site that will recognize the mRNA codon for that amino acid.

Polymerization of the amino acids takes place with the aid of the ribosome. A bacterial ribosome consists of two subunits, designated 30 and 50S, which combine to form the 70S ribosome. The complete ribosome is made up of three different ribosomal rRNAs and 52 different proteins (r-proteins). The smaller 30S subunit contains 21 proteins and a 16S rRNA, whereas the larger subunit has 21 proteins and two species of rRNA, 23S and 5S. The high-resolution structures of an intact 70S ribosome

(Cate et al. 1999) and the structure of the 50S (Ban et al. 1999) and 30S (Clemons et al. 1999) subunits of the ribosome have been reported. The functional elements, that is the tRNA and mRNA binding sites, of the ribosome are identified in these structures. The channel through which the extending peptide leaves the ribosome has also been visualized. Further analysis of these structures should permit detailed understanding of the chemistry taking place in this complex.

It is known that rRNA is initially transcribed as a single 30S precursor that is then processed into the three final rRNA products. The number of rRNA genes is variable; for example, in *E. coli* K-12 there are seven rRNA operons. Strains of *R. sphaeroides* have between three and five rRNA clusters (Nereng and Kaplan 1999). In *E. coli*, the ribosomal protein L7/L12 is present in four copies per ribosome, while other ribosomal proteins are present in one copy per ribosome. The genes responsible for the synthesis of the 52 r-proteins are organized into at least 20 translational units (operons) containing from 1 to 11 r-protein genes. At least six of the tRNA species are cotranscribed with rRNA species. The rates of synthesis of the 52 ribosomal proteins of *E. coli* and the three rRNA components are balanced so there is normally very little excess ribosomal protein or rRNA in the cells. The translation of ribosomal proteins from an operon can be inhibited by the proteins coded in that operon. These proteins normally bind to rRNAs but if their concentration is higher than required they will bind to their own mRNA, blocking translation. In addition, if sufficient ribosomal proteins are not present, rRNA will combine with other proteins but the complex formed will not function as ribosome (Nomura et al. 1984).

The mRNA represents only 2–3 percent of the total cellular RNA and its synthesis is controlled at the operon level. In translation of the mRNA into protein, a complex is formed between the 30S ribosomal subunit and certain protein initiation factors. The mRNA binds to the 30S subunit as does the first charged tRNA, the 'initiator' tRNA. The eubacterial initiator tRNA is N-formylmethionyl-tRNA, which binds to a site in the 30S subunit, termed the P site. The initiator tRNA appears to be methionine-tRNA for the archaebacteria. The ribosome also contains a binding site for a second charged tRNA (the A site). It is the codons found in the mRNA that determine the order of incorporation of the charged tRNAs. Once the charged tRNA binds at the A site, a peptide bond is formed between its amino group and the amino acid on the tRNA at the P site. The polypeptide chain is attached to the tRNA at the A site and the now uncharged tRNA moves to a third tRNA binding site in the ribosome referred to as the E site. The tRNA at the A site and its polypeptide chain move to the P site (translocation) as the ribosome moves to the next codon on the mRNA. The charged tRNA with the proper anticodon binds to the A site and the process of polypeptide chain elongation continues. The termination codons (UAA, UGA, and UAG) are not charged with any amino acid. When such codons appear on the mRNA, the polypeptide chain is released from the P site. Either the formyl group is removed from the first amino acid or the entire formylmethionine is removed.

PROTEIN FOLDING

The information required for the final structure of the synthesized protein resides in its primary sequence. While many proteins can spontaneously fold into their final tertiary structure, some are apparently assisted by accessory proteins referred to as chaperones. Several bacterial protein-folding chaperones have been studied in great detail. Perhaps the best studied chaperones are the GroEL/GroES chaperones, which have also been given the name chaperonins. The high-resolution structure of the GroEL/GroES complex has been determined. The complex is made up of two seven-membered rings of GroEL, each containing a central cavity (Xu et al. 1997). GroES forms a single seven-membered ring that caps one of the cavities of the GroEL complex. It is unclear exactly how targets of chaperones are recognized but exposed hydrophobic surfaces seem to be important. In many bacteria there are additional chaperones involved in protein folding. Two well-studied examples are DnaK (Hsp70) and DnaJ (Hsp40). These proteins help to limit aggregation of newly synthesized proteins (Fink 1999). They also probably function with the GroEL/GroES complex to carry out protein folding. These protein-folding chaperones also play a role in response to heat stress because they can assist in the refolding of incorrectly folded proteins.

Archaea also contain chaperones but so far have not been found to encode the GroEL/ES type. Archaeal chaperones are known to form stacked rings somewhat similar to the GroEL/ES ring. The high-resolution structure of the complex from the thermophile *Thermoplasma acidophilum* shows these ring structures (Ditzel et al. 1998). Both DnaK- and DnaJ-like chaperones have been found in archaea.

Proteins that are termed chaperones are involved in other cell functions besides protein folding; for example, chaperones are required for the secretion of proteins into or through the cell membrane. The protein SecB is required for recognition of proteins to be transported via the Sec system (Fekkes and Driessen 1998). Once SecB binds to targeted proteins it prevents them from folding and ferries them to the Sec translocation complex.

The eventual fate of almost all proteins is degradation. Interestingly, some proteins involved in the degradation of proteins form complexes similar in structure and function to GroEL/ES. ClpA and ClpP form rings that are probably required for the unfolding of proteins necessary for their degradation (Horwich et al. 1999). Another large complex involved in protein degradation

has been termed the 20S proteasome (De Mot et al. 1999). This is a large structure consisting of four, stacked seven-member rings. This structure has been found in the archaea and eukaryotes but only among the gram-positive actinomycetes in the eubacteria.

PROTEIN SECRETION

It is obvious that bacteria must have systems for the transport of proteins across the cell membrane. The characteristics of some of these systems were discussed above. In addition to transport across the cytoplasmic membrane many proteins are secreted into the surrounding medium. The systems for protein export are referred to as the type I–IV secretion systems. Two of these systems, types II and IV, utilize the previously mentioned Sec machinery. The other two are Sec-independent. These systems are distinct from those that only transport proteins across the cytoplasmic membrane because they also must include pores for transport across the cell wall.

The *E. coli* hemeolysin is an example of a protein transported by a type I secretion system. A unique characteristic of these systems is that transport across the cytoplasmic membrane is driven by an ABC transporter. ABC transporters are a superfamily of proteins that contain an ATP-binding cassette (hence ABC transporter). The type II system is best represented by the pullunase secretion system of *Klebsiella oxytoca*. This system utilizes the Sec system to target proteins but includes additional proteins for transport across the outer membrane. The type III systems have been heavily studied because of their role in pathogenesis. The system used by *Yersinia* species to export a set of proteins known as Yop proteins is a good example of the type III system (Cornelis and Wolf-Watz 1997). Interestingly, the system used to export flagellar proteins is similar to the type III system. It is possible that the type III system may have evolved from the flagella export system. The type IV pathway is not as well studied but appears to include proteins that use the Sec system to cross the cytoplasmic membrane but do not rely on proteins of the type II system to cross the outer membrane.

The regulation of cell division

Cell division requires that cells reach a certain critical mass before division begins. To complete cell division the cell must replicate its chromosome, segregate the chromosome into opposite halves of the cell, and then divide. Replication of the *E. coli* chromosome was discussed above. The mechanisms used to segregate the replicated chromosomes are not yet understood. Once this has been achieved, however, the cell can form a septum at the site where division will occur. Formation of the septum involves the recruitment of certain proteins to the approximate middle of the cell to form a ring. In *E. coli* these ring-forming proteins include MinE and FtsZ. The protein MinC is also required to keep ring formation from occurring at inappropriate sites. The septal rings must then contract to allow two separate cells to form. The process of ring formation and septation is very complex but a number of the proteins responsible for this process have been identified and their roles elucidated (Rothfield et al. 1999).

TRANSPORT OF SOLUTES INTO THE CELL

Simple and facilitated diffusion

Most small solutes can diffuse through the peptidoglycan material and many hydrophilic compounds can pass through the porins of the outer membrane of gram-negative bacteria. However, the cytoplasmic membrane of both gram-negative and gram-positive bacteria is a barrier to hydrophilic compounds, and special transport machinery must be utilized to allow nutrients to pass through this membrane fast enough to allow competitive growth rates. If a compound moves through the cytoplasmic membrane and into the cytoplasm without utilizing the transport machinery this is termed simple or passive diffusion. For most compounds, with the exception of certain hydrophobic compounds, entry via diffusion will be very slow. The rate of entry of a diffusible compound into the cytoplasm by simple diffusion is typically dependent upon its concentration in the medium. Because most compounds are present at extremely low concentrations in the environment, diffusion cannot be used for the uptake of most nutrients required for growth.

One example of diffusion in bacteria is the uptake of glycerol by facilitated diffusion. Facilitated diffusion results when the cell possesses a protein (the facilitator protein) that aids or facilitates the transport of a compound through the membrane. This facilitator protein permits the compound to be transferred down a concentration gradient from one side of the membrane to the other. The process is not directly coupled to metabolic energy and the compound cannot be accumulated against a concentration gradient but it may be altered and trapped to prevent it from leaving once it enters the cell. Once inside the bacterial cell, glycerol is phosphorylated by glycerol kinase and glycerol phosphate can accumulate within the cells. The phosphorylation is essential in order to trap glycerol in the cells, and mutants lacking glycerol kinase are not able to accumulate glycerol. Another example of a facilitator protein is provided by AqpZ, the water channel of *E. coli* (Calamita et al. 1995). This protein is related to other water channels in plants and animals as well as to the glycerol facilitator. Inactivation of aqpZ is not lethal to cells but

does limit cell growth under conditions of low osmolality (Calamita et al. 1998).

Active transport systems

Most solutes are brought into the cell by means of active transport systems that involve the use of metabolic energy. Because energy is used, these active transport systems can accumulate the compound within the cell to a concentration 1000 times greater than the concentration in the surrounding medium, greatly increasing the growth rate of the cell when nutrients are limited.

Substrates can be transported in various bacteria by several different active transport systems. Included among these are the ABC-type carriers. These are also known as periplasmic-binding protein-dependent transport systems or osmotic shock-sensitive transport systems. Examples of another type of active transport system are the chemiosmotic-driven, ion-gradient-linked permeases that use proton- or sodium-motive force to transport nutrients into the cell. The ATP and the proton-motive force systems can be differentiated by the use of inhibitors that prevent ATP from accumulating or by using proton ionophores, such as dinitrophenol (DNP), that collapse the proton gradient. A third type of transport, primarily associated with fermenting bacteria, is the phosphoenolpyruvate phosphotransferase system (PTS), where the compound is phosphorylated during transport through the cytoplasmic membrane.

ATP-BINDING CASSETTE, PERIPLASMIC-BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEMS

These transport systems in gram-negative bacteria are composed of a substrate-binding receptor protein associated with the cell periplasm plus several membrane-bound components. This has led these types of transport systems to be referred to as osmotic shock-sensitive permeases, because a cold osmotic shock causes the loss of the substrate-binding protein, which is loosely attached in the periplasmic space. In gram-positive bacteria, the substrate-binding receptor protein is represented by a lipoprotein fastened to the membrane.

A likely scenario for transport is that substrate binds to the periplasmic-binding protein, which then interacts with the membrane-associated transport complex. This causes the membrane-associated subunits to undergo conformational changes, which, in turn, cause conformational changes in the ATP-binding subunit, which is located on the inner surface of the cytoplasmic membrane. These changes cause ATP hydrolysis, which is used to drive transport. Substrates reported to be transported by this system in *E. coli* include carbohydrates such as L-arabinose, maltose, D-ribose, D-xylose, succinate, and malate, and amino acids such as leucine, isoleucine, valine, histidine, lysine, and ornithine.

A good example of this type of transport system is provided by the histidine permease system of *Salmonella typhimurium*. This system consists of a periplasmic-binding protein, HisJ and a membrane-associated complex of HisQMP2 (Liu and Ames 1998). HisQ and HisM are the membrane-spanning subunits and HisP is the ATP-binding subunit. The high-resolution structure of the HisP subunit has been solved and has provided insight into the functional characteristics of this large family of proteins (Hung et al. 1998).

ION GRADIENT-LINKED OR CHEMIOSMOTIC-DRIVEN TRANSPORT SYSTEMS

Chemiosmotic-driven transport systems use an ion gradient, such as proton- or sodium-motive force, as the energy to drive the transport of the substrate through the membrane. The use of an ion gradient distinguishes them from the binding protein-dependent systems that use the energy of ATP directly. The binding protein-dependent systems are termed primary transport because they are driven by an energy-producing event. The ion-gradient transport systems are termed secondary transport systems because they utilize gradients that typically have been formed by an energy-producing event.

The three basic types of ion-gradient transport are symport, antiport, and uniport. With symport, a single carrier simultaneously transports two substances in the same direction. Antiport involves a common carrier transporting two substances at the same time but in opposite directions. Uniport is the situation where movement is independent of any coupled ion.

Electrochemical ion-gradient permeases are usually composed of a single, very hydrophobic membrane protein. Probably the best studied protein of this type is LacY, the lactose transporter of *E. coli*. Many of the residues in this protein have been mutagenized and only a few have been shown to be essential for transport (Kaback and Wu 1997). Cys-scanning mutagenesis has also been used to provide a better understanding of interactions among the various domains of the protein and to probe structural changes during transport. However, detailed insight into the catalytic mechanism is still lacking at this point.

In some of the thermophilic *Bacillus*, such as *B. stearothermophilus*, Na^+ is used for the coupling ion for amino-acid transport. The proton-motive force as well as an inward-directed Na^+ gradient drives the transport of glutamate and aspartate. Sodium/proton glutamate transporters have been found in a number of thermophilic *Bacillus* species. However, in *Bacillus subtilis*, glutamate uptake was coupled to proton-motive force (Tolner et al. 1995). In *E. coli* and *S. typhimurium*, carbohydrate–sodium cotransport systems have been reported for melibose and proline. Carbohydrate–sodium cotransport systems are common in halophilic bacteria.

THE PHOSPHOTRANSFERASE SYSTEM

PTS uses the phosphate from phosphoenolpyruvate (PEP) for the transport and phosphorylation of incoming sugars. The phosphate group is first transferred from PEP to a nonspecific enzyme component termed enzyme I or EI. The phosphorylated EI (P-EI) transfers the phosphate to histidine residue 15 on a small, heat-stable protein, designated HPr. The phosphate is then transferred from phospho-HPr to a sugar-specific, membrane-bound enzyme II (EII) complex, which catalyzes the transport of the carbohydrate through the membrane as well as its phosphorylation.

The EII complex consists of domains termed IIA, IIB, IIC (and sometimes IID) that may exist as separate proteins or components of the same protein. The IIA and IIB protein domains are associated with the cytoplasmic side of the membrane and are involved in phosphate transfer. If these domains are located in separate proteins, the IIA domain will have the first phosphorylation site and the IIB domain will have the second phosphorylation site. The IIC protein/domain is located in the cytoplasmic membrane, possesses the carbohydrate-binding site, and is responsible for the transport of the carbohydrate through the membrane. The overall effect of the PTS is to both phosphorylate the carbohydrate and transport it into the cytoplasm of the cell.

The EI and HPr components are the nonspecific portions of the PTS system. The other, carbohydrate-specific components of the PTS transport system can be indicated by placing the name of the transported sugar after the enzyme designation. The EII protein/domain that is specific for the transport of D-glucose into the cells as glucose-6-phosphate can be designated as enzyme $EII^{Glucose}$ or II^{Glc}. Some EII PTS transport systems may have activity upon more than one carbohydrate; for example, *E. coli* enzyme II^{Man} has activity for the transport and phosphorylation of glucose, mannose, 2-deoxyglucose, glucosamine, and fructose, in that order (Saier and Reizer 1994).

Because the PTS transport system requires phosphoenolpyruvate as the initial phosphate donor it tends to be found in facultative or anaerobic bacteria that utilize the hexose diphosphate pathway (see below) and produce two PEP molecules for each hexose catabolized. PTS is common in such bacteria as *E. coli* and other enteric bacteria, *Bacillus*, *Clostridium*, *Bacteriodes*, *Staphylococcus*, *Lactobacillus*, and *Streptococcus*. It is not common in aerobic bacteria employing other catabolic pathways, such as *Arthrobacter*, *Azotobacter*, *Micrococcus*, *Pseudomonas*, *Nocardia*, or *Caulobacter*. In *E. coli*, the PTS transport system is used for the transport of such carbohydrates as mannitol, sorbitol, galactitol, glucose, glucose-mannose, fructose, and N-acetylglucosamine. Many gram-positive bacteria transport lactose, sucrose, maltose, and/or pentitols via the PTS. Alternative, non-PTS transport systems for glucose may also be present (Cvitkovitch et al. 1995).

The role of the PTS system in catabolite regulation

When presented with multiple carbon sources, most bacteria will preferentially utilize one of those carbon sources to the exclusion of other available substrates. In *E. coli* the preferred carbon source is glucose. This regulation of carbon metabolism is referred to as glucose repression or catabolite repression. One of the principal proteins involved in regulation of catabolite repression is IIA^{Glc}. When glucose and other sugars transported by the PTS are present, the HPr protein is rapidly being dephosphorylated as glucose is phosphorylated. Nonphosphorylated IIA^{Glc} will interact with, and inhibit the function of, enzymes required for metabolism of other compounds. This phenomenon is known as inducer exclusion. Examples of substrate whose metabolism is affected by inducer exclusion are maltose, lactose, melibiose, and glycerol. There are other causes of catabolite repression besides inducer exclusion. One of the main ways of achieving catabolite repression is via the small molecule, cyclic AMP (cAMP). This regulatory process is discussed below.

The HPr of *Streptococcus pyogenes* can also be phosphorylated on a serine residue (Ser-46) by a specific HPr kinase with ATP as the phosphate donor. This reaction has been found to be widespread among gram-positive bacteria but not gram-negative bacteria and even has been shown to occur in some species lacking a functional PTS. Phosphorylated HPr has some regulatory roles, regulating glucose and lactose permease activity in *Lactobacillus brevis* and inducer exclusion in *Lactococcus lactis*, and is involved in catabolite repression in *B. subtilis* (Thevenot et al. 1995).

BACTERIAL CATABOLIC PATHWAYS

The hexose diphosphate pathway

A very efficient pathway for the production of ATP during the catabolism of D-glucose and similar carbohydrates is often referred to as the EMP pathway to honor three scientists who contributed greatly to its elucidation, Embden, Meyerhof, and Parnas. One of the unique things about this pathway is the formation of a hexose diphosphate as an intermediate. Therefore, an alternative and descriptive name is the hexose diphosphate or HDP pathway (Figure 4).

THE PHOSPHORYLATION OF GLUCOSE

The catabolism of glucose by the HDP pathways begins by phosphorylation at the 6-carbon position. Various mechanisms have been reported for this reaction. If glucose is transported into the cells via the PTS, this

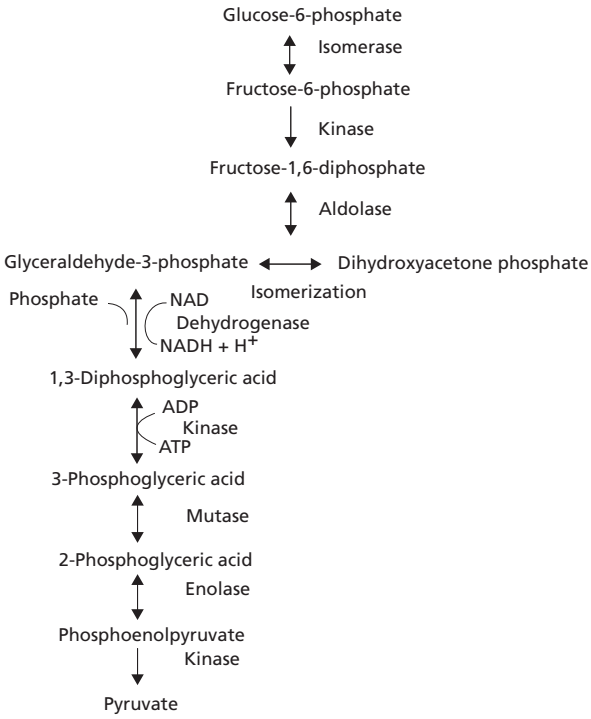

Figure 4 *The hexose diphosphate (HDP) or Embden, Meyerhof, and Parnas (EMP) pathway. Glucose-6-phosphate is converted to fructose-1,6-diphosphate, which is cleaved to produce the 3-carbon triose phosphates. Glyceraldehyde-3-phosphate is oxidized and the product of the oxidation converted to pyruvate.*

efficient transport system will convert glucose to the 6-phosphate upon passage through the cell membrane. If glucose enters the cell by a different transport system or is produced within the cell, it must be phosphorylated by other means. Hexokinase is a nonspecific kinase found in a variety of microorganisms. It can catalyze the phosphorylation of hexoses such as D-glucose, D-fructose, D-mannose, and D-glucosamine to the 6-phosphate, with ATP as the phosphate donor. Some bacteria, such as those in the genera *Staphylococcus*, *Streptococcus*, *Clostridium*, and *Lactobacillus*, possess a glucokinase that is specific for the phosphorylation of glucose to glucose-6-phosphate. At least some bacteria in the genus *Propionibacterium* can phosphorylate glucose using inorganic pyrophosphate as the phosphate donor. Transfer enzymes have been reported, which can transfer the phosphate group from a different hexose phosphate to glucose.

CONVERSION OF GLUCOSE-6-PHOSPHATE TO GLYCERALDEHYDE-3-PHOSPHATE

The reactions of the HDP pathway resulting in the conversion of glucose-6-phosphate to the two triose phosphates, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate, are illustrated in Figure 4. The first step is the isomerization of glucose-6-phosphate to the 2-ketosugar, fructose-6-phosphate. The enzyme catalyzing the reaction is glucose-6-phosphate (fructose-6-phosphate) isomerase. The equilibrium of this reaction is towards glucose-6-phosphate. However, the equilibrium of the next reaction, the conversion of fructose-6-phosphate to fructose-1,6-bisphosphate, is strongly towards product formation. The phosphorylating enzyme is phosphofructokinase (Pfk) and ATP normally is the phosphate donor. Two isozymes for Pfk have been found in *E. coli*. Most (90 percent) of the activity is provided by Pfk-1, an enzyme that is activated by nucleotide diphosphates such as ADP and inhibited by PEP. However, excess ATP and PEP are negative effectors of the enzyme and inhibit activity. Thus, the activity of the enzyme (and the HDP pathway) will be inhibited in cells with high energy charges (high levels of nucleotide triphosphates). The second enzyme, Pfk-2, is inhibited by ATP and the product of the reaction, fructose-1,6-bisphosphate.

Aldolase catalyzes the cleavage of fructose-1,6-bisphosphate to the two triose phosphates, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate, as shown in Figure 4. The equilibrium of the reaction is back towards fructose-1,6 bisphosphate so that an accumulation of triose phosphates will lead to an accumulation of fructose-1,6 bisphosphate. The accumulation of this hexose diphosphate often serves as a regulatory signal that the oxidation of glyceraldehyde-3-phosphate is not functioning properly. Dihydroxyacetone phosphate is converted to glyceraldehyde-3-phosphate by the enzyme triosphosphate isomerase.

CONVERSION OF GLYCERALDEHYDE-3-PHOSPHATE TO PYRUVATE

The next reaction of the hexose diphosphate pathway involves the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglyceric acid. This oxidation is catalyzed by glyceraldehyde-3-phosphate dehydrogenase. The 1,3-diphosphoglyceric acid contains energy in an energy-rich bond between phosphoglyceric acid and phosphate. This reaction is reversible and nicotinamide adenine dinucleotide (NAD) is usually (not always) the electron acceptor. Inorganic phosphate is the phosphate donor.

ATP-phosphoglyceric transphosphorylase, also known as phosphoglycerate kinase, catalyzes the reversible transfer of the energy-rich phosphate at the one carbon of 1,3-diphosphoglyceric acid to ADP, to form ATP and 3-phosphoglyceric acid. Phosphate esterification in this manner, with the phosphate group being transferred to ADP to form ATP, is termed substrate-level phosphorylation. Another enzyme, phosphoglycerate mutase, catalyzes the transfer of phosphate from the 3 to the 2 position of glyceric acid, producing 2-phosphoglyceric acid. Then 2-phosphoglyceric acid dehydrase, also known as enolase, removes water from 2-phosphoglycerate to form PEP, which has the highest group-transfer potential of any intermediate produced by the HDP pathway. Pyruvate kinase transfers the phosphate to ADP to form ATP and pyruvic acid.

Two isozymes of pyruvate kinase have been reported in *E. coli*. They are Pyk-F, activated by fructose 1,6-bisphosphate, and Pyk-A, activated by AMP. Mutants lacking one of these two enzymes can still grow on glucose but mutants lacking both enzymes grow poorly on glucose, except aerobically on substrates transported into the cells by the PTS (Ponce et al. 1995). In the latter case, pyruvate is generated from PEP during substrate transport. The net gain of energy from the HDP pathway is two ATP for each glucose catabolized. This pathway is an efficient pathway for the fermentation of hexoses and is common in fermenting bacteria.

THE PYRUVATE DEHYDROGENASE COMPLEX

The pyruvate dehydrogenase complex (PDH) is a multienzyme complex that catalyzes the decarboxylation of pyruvic acid and an acetyl transfer from pyruvate to coenzyme A. The complex has a structural core of dihydrolipoate transacetylase (E2) components surrounded by independently bound pyruvate dehydrogenase (E1) and dihydrolipoate dehydrogenase (E3). The cofactor requirements of the complex include lipoic acid (dithiooctanoic acid), coenzyme A, NAD, flavine adenine dinucleotide (FAD), and thiamine pyrophosphate (TPP). The products of the reaction of the complex are CO_2, acetyl-CoA, and NADH.

The complex isolated from *E. coli* possesses a chain ratio of 1.0E1/1.0E2/0.5E3 with a core of 24 E2 chains. The genes encoding for the E1, E2, and E3 enzymes (*aceE*, *aceF*, and *ipdA*) are part of the same operon. The E3, the *ipd* gene product, is also a component of the α-ketoglutarate dehydrogenase complex of the tricarboxylic acid (TCA) cycle. The E1 and E3 subunits are assembled around an icosahedral core composed of E2 polypeptides and form the complex with its molecular size of about 10 MDa (Hiromasa et al. 1994).

This pyruvate dehydrogenase from *E. coli* is stimulated by HDP intermediates such as fructose-6-phosphate. It is inhibited by a high-adenylate energy charge but such inhibition is overcome by fructose-1,6-bisphosphate. The ratio of NADH/NAD seems to influence the flow of pyruvate between pyruvate–formate lyase and the PDH complex. The activity of the complex increases with increased NAD^+ concentration within the cells but is inhibited when intracellular NADH levels are high, such high levels indicating a problem in the disposal of electrons (Snoep et al. 1991). For these reasons, utilization of the system tends to increase under aerobic conditions or when the oxidation of NADH is not a problem for the cells.

The tricarboxylic acid cycle or citric acid cycle

The TCA cycle, also known as the citric acid cycle or the Krebs cycle, is a means of oxidizing acetate (as acetyl-CoA produced by the HDP pathway) to CO_2 and electrons. The TCA cycle reactions have both anabolic and catabolic functions in many bacteria. The acetyl group from acetyl-CoA is transferred by citrate synthase to the α-keto, 4-carbon dicarboxylic acid, oxaloacetate, to form citric acid. The methyl carbon of the acetyl moiety is attached to the 2 or α-carbon of the oxaloacetate with the keto-group of oxaloacetate becoming a hydroxyl group. This hydroxyl group is transferred to a different carbon by isocitrate isomerase (aconitase) with the formation of isocitric acid. This hydroxyl group is then oxidized to an α-keto group by isocitrate dehydrogenase with the formation of oxalosuccinic acid. Oxalosuccinic acid is further oxidized with decarboxylation by isocitrate dehydrogenase to form α-ketoglutaric acid, a compound that is important in anabolic pathways. Reactions of the TCA cycle are shown in Figure 5.

In the catabolic TCA cycle, α-ketoglutaric acid is oxidized and decarboxylated by an α-ketoglutarate dehydrogenase enzyme complex, involving coenzyme A and lipoic acid. This complex is similar to the pyruvate dehydrogenase complex described previously, with CO_2 produced and a lipoic succinyl intermediate formed. The succinyl group is transferred to coenzyme A to give succinyl-CoA, which can be converted to succinic acid with the formation of a high-energy bond (ATP) in a manner similar to the formation of acetate from acetyl-CoA. Succinic acid is then oxidized to fumarate by succinate dehydrogenase with the reduction of a FAD^+ to $FADH_2$.

Succinate dehydrogenase (SDA) is a membrane-bound enzyme that is part of the respiratory chain and appears to be present in all aerobic cells. It is composed of two subunits, a flavoprotein (FP) and an iron sulfur

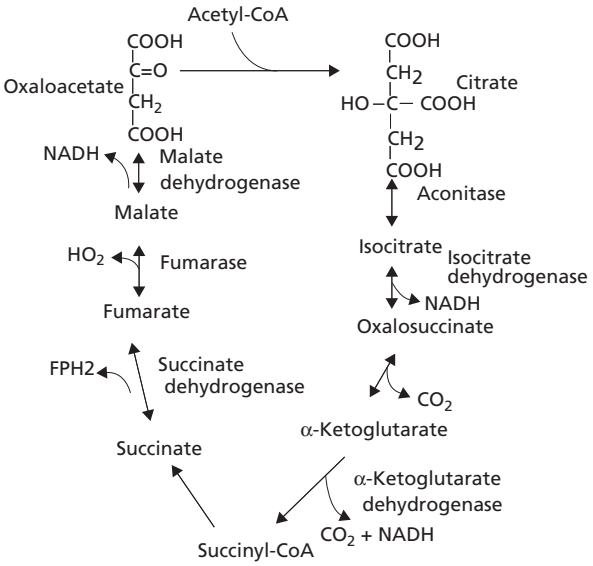

Figure 5 *The tricarboxylic acid cycle, showing the reactions resulting in the oxidation of acetate to carbon dioxide*

protein and, in prokaryotic cells, SDH is fastened to the inner side of the cytoplasmic membrane by a cytochrome. While the high-resolution structure of SDH has not been determined, the structure of fumarate reductase, which catalyzes the reverse reaction and has extensive structural and sequence similarity to SDH, has been determined (Iverson et al. 1999). Fumarate is hydrated by malate dehydrase (fumarase) to form malate, malate is oxidized by malate dehydrogenase to produce oxaloacetic acid, and the cycle is complete. For each acetate oxidized, provided as acetyl-CoA, two molecules of CO_2 and eight pairs of electrons are obtained. Two of these electrons are transported to FAD^+ and six to NAD^+. An ATP can be obtained from the succinyl-CoA.

Succinate and oxaloacetate, as well as α-ketoglutarate, are important compounds in biosynthetic reactions. Even anaerobic bacteria, which do not utilize the TCA cycle for complete oxidation of acetate, may need TCA-cycle enzymes for biosynthetic reactions. However, it would not be efficient for anaerobic bacteria to oxidize acetate completely because they would have difficulty in disposing of the electrons. Such bacteria often lack the α-ketoglutarate enzyme complex. This complex, usually missing in anaerobes, is known as the 'anaerobic lesion' of the TCA cycle.

Growth on acetate as a carbon source

E. coli has two pathways that can be used to convert acetate to acetyl-CoA. One pathway uses acetate kinase and ATP to produce acetyl phosphate, then phosphotransacetylase transfers the acetyl moiety from acetyl phosphate to CoA to form acetyl-CoA. However, this route is believed to function primarily in a catabolic role, generating ATP when acetate is being excreted. This system would be used to activate acetate only when acetate was present in large amounts outside the cells. The second pathway is believed to function by using extracellular acetate that is present in low concentrations. It uses the enzyme acetyl-CoA synthetase to convert acetate and ATP to acetyl-AMP and inorganic pyrophosphate. The acetyl-AMP reacts with CoA to release inorganic phosphate and form acetyl-CoA. Although wild-type *E. coli* cells grow well on acetate at concentrations ranging from 2.5 to 50 mM, mutants lacking acetyl-CoA synthetase grow poorly on low acetate concentrations. Mutants lacking acetate kinase and phosphotransacetylase grow poorly on high concentrations of acetate, and mutants lacking all three enzymes did not grow on acetate at any concentration tested (Kumari et al. 1995).

When growing on acetate as the sole carbon source, bacteria must have the enzyme capability to reverse the HDP pathway and form pentoses and hexoses from these simple 2- and 3-carbon compounds. While some strict anaerobes are able to reverse the pyruvate:ferredoxin oxidoreductase reaction to form pyruvate from CO_2 and acetate, most bacteria that can grow with only acetate as the carbon source incorporate it into TCA-cycle intermediates (see Figure 5) by a series of reactions known as the glyoxylate bypass or glyoxylate cycle. During the glyoxylate cycle the acetyl-CoA produced by acetyl-CoA synthetase is combined with a molecule of existing oxaloacetic acid to form citrate and the citrate is isomerized to isocitrate by normal TCA cycle enzymes. A unique enzyme, isocitrate lyase, cleaves the isocitrate to produce succinate and glyoxylate. The glyoxylate is condensed with acetyl-CoA by the enzyme malate synthase to form malate, as shown in Figure 6. In this manner, one oxaloacetate and two acetyl groups have been converted to malate and succinate. These latter two compounds can be oxidized and converted to two oxaloacetates so the overall series of reactions form two oxaloacetates from one oxaloacetate and two acetates. Oxaloacetate can be used to form other TCA intermediates for biosynthetic purposes or can be decarboxylated to PEP by the enzyme phosphoenolpyruvate carboxykinase.

The genes coding for isocitrate lyase and malate synthase are located in the same operon in *E. coli* and the synthesis of the enzymes is regulated so they are formed when two carbon intermediates are the sole source of carbon. The enzymes of the bypass are induced by acetate and repressed by most other carbon compounds. In *E. coli* the flow of isocitrate through the glyoxylate bypass, rather than the TCA cycle, is controlled by activation and deactivation of isocitrate dehydrogenase. When bacteria are grown on glucose, isocitrate dehydrogenase is fully operational, but when cells are grown on acetate, the activity of the enzyme is decreased by 70 percent (Chung et al. 1988). This decrease is the result of the enzyme being phosphorylated at its active site by isocitrate dehydrogenase kinase/phosphatase (Hurley et al. 1990). The gene encoding the kinase/phosphatase is in the same operon

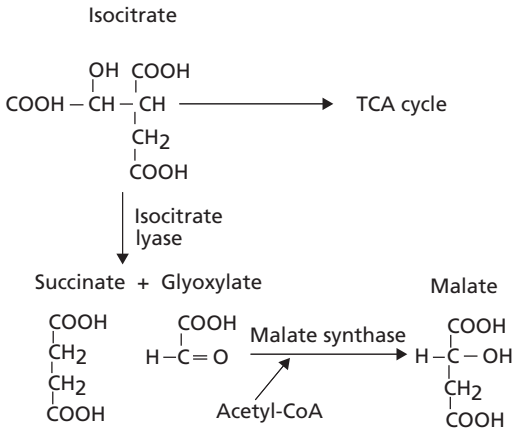

Figure 6 *Reactions of the glyoxylate bypass. Oxaloacetate and acetate are converted to citrate and then isocitrate. The isocitrate is cleaved to succinate and glyoxylate and the glyoxylate is combined with another acetate to yield malate.*

as the genes encoding isocitrate lyase and malate synthase. Some strains of *E. coli* cannot grow on acetate without the expression of this regulatory enzyme (Cortay et al. 1988).

If pyruvate or lactate are substrates, *E. coli* can use the enzyme phosphoenolpyruvate synthase and ATP to convert pyruvate to PEP, with AMP and inorganic phosphate as products. The HDP pathway can then be reversed (glucogenesis) to fructose-1,6-bisphosphate and a phosphatase can cleave phosphate from the 1-carbon position to yield fructose-6-phosphate. The PEP also can be combined with CO_2 (phosphoenolpyruvate carboxylase) to form oxaloacetate, which can be converted to other TCA-cycle intermediates.

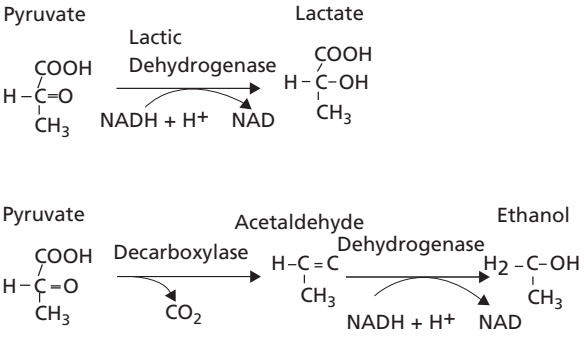

Figure 7 *Formation of lactate and ethanol from pyruvate. Pyruvate can be directly reduced to lactate or decarboxylated to acetaldehyde, which can be reduced to ethanol.*

The glucose fermentations

In microbial physiology and metabolism the term 'fermentation' has a very specific meaning, i.e. the condition where the final electron acceptor of a catabolic pathway is an organic compound. An example of a process where this is important is in the oxidation of reduced NAD^+ produced by the HDP pathway. The NAD^+ reduced by the oxidation of glyceraldehyde-3-phosphate during the HDP pathway must be reoxidized if the pathway is to continue functioning. Therefore, fermentation is a process that can keep the HDP pathway functioning if no other electron acceptors are available. It should be pointed out that in industry the term 'fermentation' is used to denote many metabolic reactions caused by microorganisms, not just the specific definition described above.

THE HOMOLACTIC ACID FERMENTATION

Pyruvate, produced as a result of the HDP pathway, is an excellent acceptor for the electrons produced by the oxidation of glyceraldehyde-3-phosphate and most bacteria possess the metabolic capability of reducing pyruvate to lactic acid (see Figure 7). For some bacteria the reduction of pyruvate to lactate is the most important method of reoxidizing NADH and such bacteria produce large amounts of lactic acid as final products of glucose fermentation. For this reason, such bacteria are termed 'lactic-acid bacteria.' If glucose is the only carbon source provided to the cells, some of the products of glucose degradation by the HDP must be used for biosynthetic purposes to make new cell material. However, because the energy gained as a result of fermentation is relatively low, most of the carbon from the glucose must be converted to fermentation products. The term 'homolactic acid fermentation' means that significantly more than half of the carbon from the glucose fermented is in the form of lactic acid. It is apparent that any bacterium that carries out a homolactic acid fermentation must be able to survive in the presence of a large amount of lactic acid and at low pH.

Lactic acid is the major product of the homolactic acid fermentation but other products may be formed in lesser amounts. Many homolactic-acid bacteria produce such fermentation products as acetate, ethanol, and formate, in addition to lactate. The conversion of pyruvate to formic acid, ethanol, and acetic acid rather than lactose actually increases the energy gained by the fermentation, but it also increases the amount of acid formed. Regulatory systems of homolactic-acid bacteria tend to shift the fermentation to larger amounts of these compounds at higher pH values, where acid production would be less likely to inhibit growth.

The purification of lactic acid dehydrogenase from a homolactic-acid bacterium led to the discovery that this enzyme was an allosteric enzyme with an absolute requirement for a positive effector. If the reduction of pyruvate to lactic acid does not proceed efficiently enough to reoxidize the NADH formed from the oxidation of glyceraldehyde-3-phosphate, the oxidation of the triose phosphate is inhibited. Because of the reversibility of the aldolase-catalyzed reaction, the internal pool of the positive effector of lactic acid dehydrogenase, fructose-1,6-bisphosphate, increases. This results in the activation of more molecules of lactic acid dehydrogenase and the more rapid reduction of pyruvate.

THE DIRECT ALCOHOL FERMENTATION

The direct alcohol fermentation or 'yeast type' of alcohol fermentation permits the oxidation of NADH from the HDP pathway without the formation of large amounts of lactic acid. Pyruvate is directly decarboxylated by pyruvate decarboxylase to yield acetaldehyde and CO_2. The enzyme alcohol dehydrogenase catalyzes the reduction of acetaldehyde to ethyl alcohol with electrons from NADH (see Figure 7). This mechanism of ethanol formation is common in yeast but, although many bacteria are capable of ethanol production, only a few do so by this pathway. Some of those bacteria using this yeast type of pathway for ethanol formation include those in the genera *Zymomonas*, *Acetomonas*, and *Sarcina ventriculi*.

THE FORMIC ACID FERMENTATION

Some bacteria have evolved the ability to obtain extra energy from pyruvate. In one mechanism for pyruvate fermentation, the enzyme pyruvate formate–lyase cleaves pyruvate to formic acid and a 2-carbon fragment that becomes acetyl-CoA. This enzyme is present in either an active or inactive state, with the active state having a free radical at its C-terminus (Sawers and Watson 1998). The cleavage of *S*-adenosylmethionine into methionine and 5′-deoxyadenosine is required for enzyme activation. The active form of the enzyme normally functions only under anaerobic conditions and is rapidly and irreversibly inactivated by oxygen (Sawer and Bock 1988). This enzyme is common in enteric bacteria and also accounts for the formic acid produced during some homolactic acid fermentations.

When pyruvate formate–lyase is active the NADH produced by the HDP pathway cannot be reoxidized by lactic-acid production. Instead, some of the acetyl group on the acetyl-CoA is reduced twice, first to acetaldehyde and then to ethanol. This reduction is catalyzed by a special alcohol dehydrogenase, a CoA-linked alcohol dehydrogenase. The energy of the acetyl-CoA bond is sacrificed in the reaction but two NADH can be oxidized for each ethanol produced. Facultative bacteria, such as *E. coli*, have a single large polypeptide responsible for both reductions. The *adhE* gene of *E. coli*, K-12, encodes a polypeptide of 891 amino acids, equivalent in size to a combined alcohol dehydrogenase and an acetaldehyde dehydrogenase, and may represent an evolutionary fusion product of separate genes. Some obligate anaerobes, such as *Clostridium*, have two proteins to catalyze the reduction of acetyl-CoA to ethanol, a CoA-linked acetaldehyde dehydrogenase and an alcohol dehydrogenase. These two separate polypeptides form a complex so that free acetaldehyde is not released.

The acetyl-CoA that is not needed for the oxidation of NADH can be used for the generation of additional ATP. The enzyme phosphotransacetylase catalyses the reversible transfer of acetate from acetyl-CoA to phosphate with the formation of acetyl phosphate. The enzyme acetate kinase, in a reaction that is also reversible, transfers the phosphate from acetyl phosphate to ADP, to form ATP and liberate acetate. Therefore, two pyruvate and two NADH can result in two formate, one ethanol and one acetate, with the gain of one ATP. This fermentation is also known as the mixed-acid fermentation and the metabolic reactions leading to these products are illustrated in Figure 8.

Mutants of *E. coli* lacking lactic dehydrogenase grow normally under anaerobic conditions, but if these mutants also lack pyruvate formate–lyase they cannot grow by fermenting glucose or other sugars (Mat-Jan et al. 1989). If mutants of *E. coli* lack the ability to produce ethanol from acetyl-CoA, they cannot grow anaerobically on glucose unless provided with some alternative electron acceptor such as nitrate. However, an additional mutation also eliminating the pyruvate formate–lyase enzyme will restore the ability to grow on glucose anaerobically, with the cells now producing lactic acid.

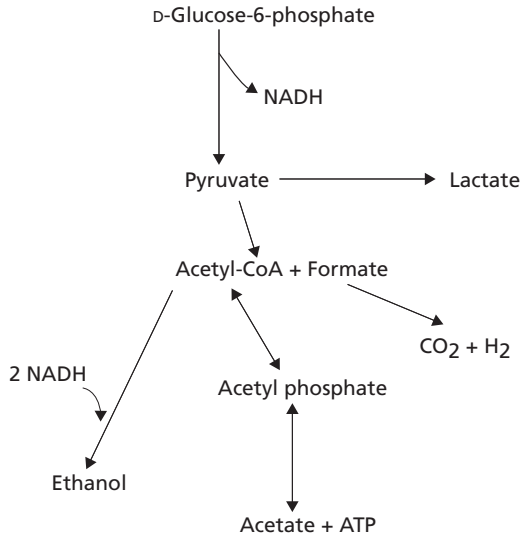

Figure 8 *Possible products of the formic-acid or mixed-acid fermentation. Pyruvate can be cleaved to yield acetyl-coenzyme A (acetyl-CoA) and formate. The acetyl-CoA can be converted to acetate, yielding a high-energy phosphate bond, or reduced to ethanol. If the proper enzymes are present, the formate can be oxidized to yield carbon dioxide and hydrogen gases.*

BUTANEDIOL FORMATION

Some bacteria, for example some bacilli, have developed a pathway for the degradation of pyruvate that produces less acid. An α-acetolactate-synthesizing enzyme with a pH optimum at 6.0 converts two pyruvates to α-acetolactate and CO_2. This enzyme is sometimes named the pH 6.0 α-acetolactate-synthesizing enzyme to distinguish it from a biosynthetic enzyme that carries out the same reaction but possesses a pH optimum of 8.0. During the fermentative pathway the α-acetolactate is decarboxylated by α-acetolactate decarboxylase to produce another CO_2 and acetoin. The acetoin produced can be reduced to 2,3-butanediol by the action of butanediol dehydrogenase and the oxidation of NADH. This system of enzymes appears to be induced by acetate and at high pH values it is inhibited from operating (Zeng and Deckwer 1991). Because this pathway utilizes two pyruvate and results in the oxidation of only one NADH, it cannot be the sole fermentation route of glucose by a microorganism. The advantage of this pathway is the production of neutral products.

BUTYRATE AND BUTANOL FERMENTATION

In many strictly anaerobic bacteria and archaea, the oxidation and decarboxylation of pyruvate are catalyzed

by pyruvate:ferredoxin oxidoreductase, an enzyme that catalyzes the oxidation of pyruvate to form acetyl-CoA and CO_2. The electrons are placed on the electron carrier ferredoxin, which may donate them to a hydrogenase with the eventual formation of hydrogen (H_2) gas. The class of electron carriers known as ferredoxins comprises small (6–13 kDa), iron–sulfur ([Fe-S]) proteins that function in a variety of reactions, including nitrogen fixation and photosynthesis.

The acetyl group from the acetyl-CoA obtained by the action of pyruvate:ferredoxin oxidoreductase can be used for the production of acetate and ATP, via phosphotransacetylase and acetate kinase, or utilized to generate electron acceptors for the NADH formed by the HDP pathway. In some bacteria, such as those of the genus *Clostridium*, an enzyme named acetyl coenzyme A acetyl transferase condenses two molecules of acetyl-CoA to produce one molecule of acetoacetyl-CoA. This latter compound can be reduced by β-hydroxybutyryl coenzyme A dehydrogenase and NADH to produce β-hydroxybutyryl-CoA. This latter compound can be dehydrated by 3-hydroxyacyl coenzyme A hydrolase (crotonase) to form crotonyl-CoA. The double bond in crotonyl-CoA is further reduced by butyl coenzyme A dehydrogenase to butyryl coenzyme A with electrons again coming from NADH. Thus, the overall series of reactions decarboxylates two pyruvates, with the acetyl groups becoming condensed into a four-carbon compound that undergoes two reduction steps to form butyryl-CoA.

The butyryl-CoA can have different fates. Acetyl transferase may transfer a free acetate on to the CoA group, producing acetyl-CoA and yielding free butyric acid. A second possibility is for phosphotransbutyrylase to transfer the butyryl group to phosphate to form butyryl phosphate. The phosphate can be donated to ADP to form ATP. Some clostridia produce free acetoacetate from acetoacetyl-CoA by replacing the acetoacetate with acetate. The free acetoacetate can be decarboxylated by acetoacetyl decarboxylase, producing acetone and CO_2, and the acetone may be reduced by isopropyl dehydrogenase yielding isopropyl alcohol.

The propionic acid fermentations

Some bacteria, for example those in the genera *Propionibacterium*, *Veillonella*, and *Bacteriodes*, produce propionic acid as a fermentation product. These bacteria can ferment lactic acid because reducing reactions involved in the production of propionic acid permit the oxidation of lactic acid to pyruvic acid. Some of the pyruvate formed as a result of fermentation is usually decarboxylated to yield acetate and CO_2. An additional product of this fermentation is succinic acid.

Oxaloacetate is an intermediate in the formation of propionate. To synthesize this four-carbon compound, a carboxyl group is recycled during the fermentation. The carboxyl group is transferred to the three-carbon compound pyruvate. The enzyme catalyzing this reaction is methylmalonyl-CoA-pyruvate transcarboxylase. The reduction of the oxaloacetate to malate, its conversion to fumarate, and the reduction of the fumarate to succinate can be used to dispose of electrons, such as those obtained from the HDP pathway or the oxidation of lactic acid. A CoA-transferase enzyme exchanges the succinate with the propionyl group on a molecule of propionyl-CoA to form free propionic acid and succinyl-CoA. An isomerase then converts the succinyl-CoA to methylmalonyl-CoA, which donates a carboxyl group to the enzyme–biotin complex to form a biotin–ADP–CO_2 complex and a molecule of propionyl-CoA. The activated carboxyl group is used to convert another pyruvate to oxaloacetate while propionic acid is liberated during the activation of another succinate. While this reaction is taking place, pyruvate is also being converted to acetate to balance the overall fermentation. By these reactions, a typical propionic acid bacterium such as *P. pentosoccium* will produce CO_2, acetic acid, propionic acid, and succinic acid as a result of glucose or lactic acid fermentation.

Clostridium propionicum also produces propionic acid as a fermentation product but the pathway differs from those above. Pyruvate is converted to propionic acid by a direct reduction route, involving reduction to lactate that is used to form lactyl-CoA. This latter compound is dehydrated, and reduced to propionyl-CoA. There is no formation of a four-carbon compound during this fermentation.

Another interesting use of oxaloacetate is as substrate for the Na^+-oxaloacetate decarboxylase, which is a membrane-bound Na^+ pump. The free energy of decarboxylation is sufficient to drive the development of a sodium gradient. This sodium gradient can be used to generate ATP by taking advantage of the electrochemical sodium gradient (see below). An example of a bacterium carrying out this reaction is *Propionibacterium modestum*, a strict anaerobe isolated from salt water.

The fermentation of ethanol

Some bacteria such as *Clostridum kluyveri* are able to gain energy by the fermentation of ethanol. Ethanol is oxidized and activated to form acetyl-CoA and the production of H_2 and the formation of fatty acids eliminate the electrons obtained by this oxidation. Two acetyl-CoA molecules are condensed to form acetoacetyl-CoA and this compound proceeds through the metabolic pathways described previously with two reduction steps giving butyryl-CoA. Additional acetyl molecules may be added with the production of larger fatty acids as final products. Pyruvate is synthesized by reversal of pyruvate:ferredoxin oxidoreductase.

The fermentation of pentoses

CONVERSION OF PENTOSES TO INTERMEDIATES OF THE HDP PATHWAY

Some bacteria are able to ferment certain 5-carbon sugars such as D-xylose and L-arabinose. The fermentation route of these pentoses by enteric bacteria generally involves isomerization of the aldopentose to the 2-keto-isomer or pentulose. A pentulose kinase then catalyzes phosphorylation to form the pentulose-5-phosphate. In such a manner, D-xylose is isomerized to D-xylulose and then phosphorylated to D-xylulose-5-phosphate, while L-arabinose is isomerized to L-ribulose and then phosphorylated to L-ribulose-5-phosphate. Epimerization reactions convert the pentulose-5-phosphates to D-xylulose-5-phosphate, which represents the common intermediate in the catabolism of these sugars. The exception is d-ribose, which is usually phosphorylated first and then isomerized to D-ribulose-5-phosphate.

The pentulose phosphates are converted to intermediates of the HDP pathway by a series of reactions known as the transketolase/transaldolase rearrangements. The enzyme transketolase (TK) cleaves 2-keto-sugars such as D-xylulose-5-phosphate between the 2- and 4-carbons and transfers the 2-carbon group to a proper aldehyde receptor, such as D-ribulose-5-phosphate, forming glyceraldehyde-3-phosphate and the seven-carbon carbohydrate sedoheptulose-7-phosphate. Transaldolase (TA) cleaves similar carbohydrates between the 3- and 4-carbons, transferring the 3-carbon moiety to an appropriate acceptor such as glyceraldehyde-3-phosphate. These rearrangements convert the 5-carbon sugar phosphate to intermediates of the HDP pathway such as glyceraldehyde-3-phosphate and fructose-6-phosphates with four- and seven-carbon carbohydrates as intermediates. The structures of some substrates and products of the TK/TA rearrangements are shown in Figure 9.

The conventional HDP pathway enzymes will convert glyceraldehyde-3-phosphate to pyruvate with the production of normal fermentation products. Because these enzyme-catalyzed reactions are reversible, pentose also can be synthesized from HDP pathway intermediates.

THE HEXOSE MONOPHOSPHATE OR PENTOSE PHOSPHATE PATHWAY

Many bacteria, including *E. coli*, can oxidize glucose-6-phosphate at the 1-carbon to form 6-phosphogluconic acid, which is then converted to a 5-carbon compound and metabolized using the TK and TA reactions. The enzyme that oxidizes glucose-6-phosphate, glucose-6-phosphate dehydrogenase, normally uses NADP, rather than NAD, as the electron acceptor. The 6-phosphogluconolactone formed by this reaction is converted to 6-phosphogluconate by a lactonase. The 6-phosphogluconate can be further oxidized and decarboxylated by 6-phosphogluconate dehydrogenase to produce CO_2, D-ribulose-5-phosphate, and, usually, NADPH. In many bacteria, such as the enterics, this is primarily a biosynthetic route, providing the cells with pentose for RNA and DNA synthesis and NADPH for biosynthetic reducing power, and in aerobically growing *E. coli*, about 15 percent of the glucose is diverted to pentoses by this route. However, the pathway can be used for glucose catabolism with the pentose phosphates converted to HDP intermediates via the TK/TA rearrangements. This route of glucose catabolism does not involve a sugar diphosphate as an intermediate and is known as the hexose monophosphate pathway (HMP) or sometimes the pentose phosphate pathway. With an *E. coli* mutant unable to use the HDP, such as a glucose-6-phosphate isomerase-negative mutant, the cells can still grow on glucose using the HMP pathway, but at a slower rate than when the HDP pathway is employed. Some bacteria, such as *Thiobacillus novellus* and *Brucella abortus*, use only the HMP pathway for glucose metabolism.

Because fructose-6-phosphate can be one of the products produced from pentulose phosphate by the TK/TA reactions, the potential exists for some organisms to convert fructose-6-phosphate to glucose-6-phosphate and oxidize this compound to 6-phosphogluconate and then to ribulose-5-phosphate. In such a manner an HMP

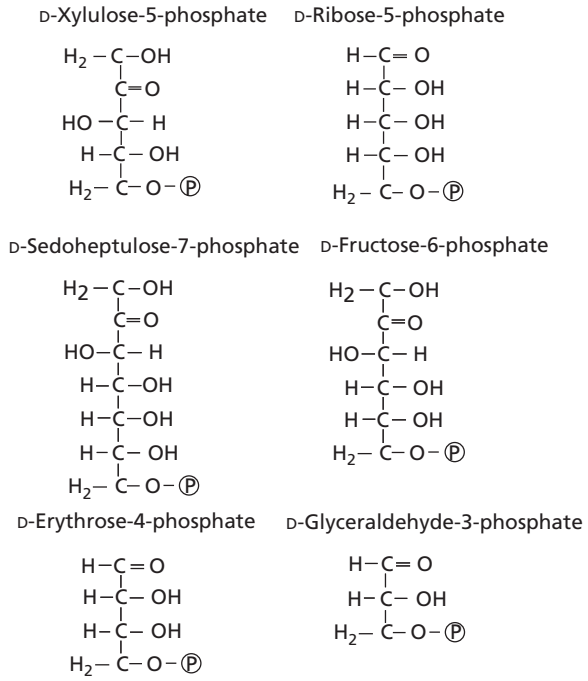

Figure 9 *Carbohydrates involved in the transketolase/transaldolase reactions. D-Xylulose-5-phosphate, D-fructose-6-phosphate, and D-sedoheptulose-7-phosphate can serve as substrates to be cleaved by transketolase or transaldolase. D-Glyceraldehyde-3-phosphate, D-erythrose-4-phosphate, and D-ribose-5-phosphate can serve as acceptors for the 2- or 3-carbon moiety being transferred.*

cycle may exist, with the oxidation of hexoses not requiring the oxidation of glyceraldehyde-3-phosphate.

THE HETEROLACTIC ACID FERMENTATION PATHWAY

A bacterium using the HDP pathway to ferment glucose to pyruvate can gain two ATP per glucose used by substrate-level phosphorylation, but the energy yield is less for the fermentation of a pentose. Theoretically, a homolactic acid fermenter using the HDP pathway could gain six ATP by the fermentation of three glucose to six lactate. However, it could only gain five ATP by the fermentation of three pentoses to five lactate using the pentose phosphate route and the TK/TA rearrangements.

Some lactic-acid bacteria have evolved a more efficient pathway for the fermentation of 5-carbon sugars. Instead of the D-xylulose-5-phosphate being cleaved by TK, it is cleaved by an enzyme termed phosphoketolase in a reaction that results in the esterification of inorganic phosphate and the formation of glyceraldehyde-3-phosphate and acetyl phosphate as products. The glyceraldehyde-3-phosphate can be converted to pyruvate by normal HDP pathway enzymes, yielding a gain of two ATP. The acetyl phosphate can be used to phosphorylate ADP to generate an ATP through the action of acetate kinase. Because one ATP is used to form the pentulose phosphate, the result is a net gain of two high-energy phosphate bonds for each pentose fermented. Bacteria that possess this fermentation route for pentoses normally possess high activity for lactic dehydrogenase and reduce most of the pyruvic acid to lactic acid. Therefore, the fermentation products from 5-carbon sugars are primarily lactate and acetate in equal amounts.

Bacteria possessing phosphoketolase are often lacking key enzymes of the hexose diphosphate pathway such as phosphofructokinase and aldolase and are unable to use the complete HDP pathway for the catabolism of glucose. If provided with D-glucose as a carbon and energy source, they use the enzymes glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase to form D-ribulose-5-phosphate and CO_2. The ribulose-5-phosphate can be epimerized to D-xylulose-5-phosphate, which is cleaved by phosphoketolase to produce glyceraldehyde-3-phosphate and acetyl phosphate. The glyceraldehyde-3-phosphate is converted to pyruvate and lactate in a normal manner for a homolactic acid fermentation. However, in order to dispose of all of the electrons from the oxidation of the six-carbon sugar to the pentulose, the acetyl phosphate must be reduced to ethanol in two reduction steps. Thus, the products of the fermentation of glucose by this route are CO_2, ethanol, and lactic acid and the energy yield is only one ATP per hexose fermented. This fermentation of glucose is termed a heterolactic acid fermentation because the three major products are produced in approximately equal amounts. The CO_2 is derived from the 1-carbon of the hexose, the ethanol from the 2- and 3-carbons, and the lactic acid from the 4-, 5-, and 6-carbons.

Bacteria in the genus *Bifidobacterium* carry out a variation of this fermentation. These bacteria also lack the aldolase of the HDP pathway but possess a fructose-6-phosphate phosphoketolase that converts fructose-6-phosphate to acetyl phosphate and erythrose-4-phosphate. The acetyl phosphate can be used for the production of ATP with acetate being liberated. The transketolase and transaldolase enzymes can act upon the erythrose-4-phosphate and fructose-6-phosphate, producing 7- and 5-carbon carbohydrates and eventually forming some glyceraldehyde-3-phosphate that can be converted to pyruvate. Thus, these bacteria ferment glucose to large amounts of acetic acid with smaller amounts of lactic acid, ethanol, and formic acid.

Alternative routes of carbohydrate catabolism

THE KDPG PATHWAY

An alternative route for the conversion of glucose to pyruvate is known as the Entner/Douderoff pathway or the 2-keto-3-deoxy-6-phosphogluconate (KDPG) pathway, because this latter compound is an intermediate unique to this metabolic route. The two enzymes unique to the KDPG route are 6-phosphogluconate dehydratase and KDPG aldolase. The first reaction of the pathway is oxidation of glucose-6-phosphate to 6-phosphogluconate by the action of glucose-6-phosphate dehydrogenase. The 6-phosphogluconate is dehydrated by 6-phosphogluconate dehydratase, to form KDPG. This latter compound is cleaved by KDPG aldolase, producing pyruvate from the first three carbons and glyceraldehyde-3-phosphate from the 4-, 5-, and 6-carbons. These two reactions are shown in Figure 10.
The pyruvate can be oxidized and decarboxylated to form acetyl-CoA and the acetyl group can be oxidized via the TCA cycle, while the glyceraldehyde-3-phosphate produced by the action of KDPG aldolase can be converted to pyruvate by the normal enzymes of the HDP pathway.

The KDPG route in enteric bacteria

The KDPG route is not normally used by *E. coli* cells catabolizing glucose but can be used when gluconic acid is the carbon source. *E. coli* catabolizes gluconate by first using gluconokinase to phosphorylate it to 6-phosphogluconate. Some of the 6-phosphogluconate may be oxidized to D-ribulose-5-phosphate and CO_2, and degraded by the HMP pentose route. Most, however, is dehydrated by 6-phosphogluconate dehydratase to KDPG, which is cleaved by KDPG aldolase. Because *E. coli* is unable to oxidize glucose to gluconate, the KDPG route is not induced when D-glucose is the substrate.

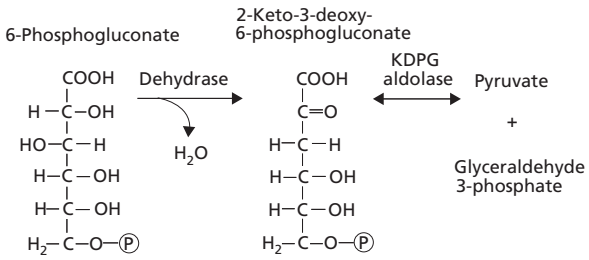

Figure 10 *Reactions of the 2-keto-3-deoxy-6-phosphogluconate (KDPG) route to pyruvate. Two reactions convert 6-phosphogluconic acid to pyruvate and glyceraldehyde-3-phosphate.*

With mutants of *E. coli* deficient in KDPG dehydratase, all gluconate must be metabolized through the pentose phosphate route. If another mutation occurs so that the organism also loses 6-phosphogluconate dehydrogenase activity, the cells cannot grow on gluconate at all.

Why does *E. coli* retain the capacity to use gluconate as a carbon source? One explanation is that it provides an advantage during growth in a specialized environment. Evidence has indicated that one such environment might be the large intestine. Mutants in which the gene encoding KDPG aldolase had been disrupted have been shown to be incapable of colonizing the large intestine of the mouse (Sweeney et al. 1996).

Analysis of the genome of *E. coli* has also revealed that there are two gluconate transporters. It has been shown, however, that one of these transporters is not used for gluconate but for the sugar acid L-idonic acid (Bausch et al. 1998). This compound is apparently transported without phosphorylation and then converted to 6-phosphogluconate. Enzymes of the KDPG pathway then metabolize the 6-phosphogluconate.

GLUCOSE CATABOLISM IN THE GENUS *PSEUDOMONAS*

The phosphorylated routes for glucose catabolism

One pathway of glucose catabolism in the pseudomonads involves phosphorylated intermediates. The phosphorylated route involves the phosphorylation of glucose to glucose-6-phosphate and its oxidation to 6-phosphogluconate. Much of the 6-phosphogluconate formed will be degraded through the KDPG route, although some may be diverted to the HMP route. Glucose-6-phosphate isomerase is usually present, and aldolase may also be present, but phosphofructokinase is often lacking or very weak, so the HDP route usually does not function

Aldolase can be present to form fructose-1,6-bisphosphate from triose phosphates; therefore, some of the pseudomonads have the ability to convert the glyceraldehyde-3-phosphate formed by KDPG aldolase back to fructose-1,6-bisphosphate. Phosphatase activity can cleave phosphate to form fructose-6-phosphate and this can be isomerized to glucose-6-phosphate, which can be oxidized and converted to KDPG. This route, from hexose phosphate to KDPG, to triose phosphate, and back to hexose phosphate, can be considered as a KDPG–hexose cycle. Some mutants blocked in the conversion of glyceraldehyde-3-phosphate to pyruvate can still grow on glucose by using this cycle (Lessie and Phibbs 1984).

In many bacteria, the oxidation of glucose-6-phosphate to 6-phosphogluconate also serves an anabolic or biosynthetic function, producing pentoses and reducing power (NADPH) for biosynthetic reactions. In aerobes where glucose-6-phosphate dehydrogenase is also an important catabolic enzyme, the reaction may need to serve both catabolic and biosynthetic purposes. In some cases, either NAD or NADP may serve as the electron acceptor for glucose-6-phosphate dehydrogenase, depending upon the needs of the cell. In other cases, isozymes may be involved in the reaction, one isozyme reducing NAD and another reducing NADP.

The route of catabolism for 5-carbon carbohydrates by pseudomonads can be similar in many ways to the KDPG route of glucose catabolism. The aldopentose substrate can be oxidized directly to a pentonic acid and a dehydration reaction can follow to form the 2-keto-3-deoxy-pentonic acid. This may be cleaved by an aldolase to yield pyruvate and glycolaldehyde with the glycolaldehyde oxidized to glycolic acid. In this manner D-xylose can be oxidized to D-xylonic acid, which can be dehydrated to 2-keto-3-deoxy-xylonic acid. In a similar manner, D-ribose can be oxidized to ribonic acid, which can be dehydrated to 2-keto-3-deoxy-ribonic acid.

The oxidative pathway for hexoses

In addition to the phosphorylated pathways for the catabolism of sugars described above, many pseudomonads also possess oxidative pathways. In these cases, flavin or cytochrome-linked, membrane-bound oxidase enzymes, located in the periplasmic space, oxidize the sugars with electrons passing from the electron acceptor directly to O_2. Glucose oxidase oxidizes glucose to form gluconate, while other oxidases can convert the gluconate to keto-sugars such as 2-ketogluconate and 2,6-diketogluconate. The glucose oxidase (sometimes called dehydrogenase) of *Pseudomonas fluorescens* was found to be a quinoprotein, whereas the gluconate oxidase was found to be a flavoprotein. Such oxidation reactions, associated with the cell membrane, provide the cells with rapid energy. Pseudomonads lacking glucose oxidase are unable to produce gluconate and cannot induce the KDPG pathway enzymes.

The keto-sugars formed by the oxidative reactions may be later transported into the cells, phosphorylated, and further degraded by phosphorylated routes. Pseudomonads lacking gluconokinase cannot form glucose-6-phosphate from glucose but may utilize the oxidized

products from the periplasm. Some pseudomonads can grow in the absence of oxygen by using nitrate as an electron acceptor. However, then they must use the direct phosphorylated pathways for catabolism because nitrate will not replace oxygen in the oxidative pathways.

If the oxygen concentration is low, the catabolism of glucose in *Pseudomonas aeruginosa* is decreased from the extracellular, direct oxidative route to the intracellular phosphorylative route. The change results in a decrease in the concentrations of glucose dehydrogenase and gluconate dehydrogenase activities and decreases the transport systems for gluconate and 2-ketogluconate, but there is increased activity for glucose transport (Mitchell and Dawes 1982). Global regulatory controls of these strict aerobes differ from those for the enteric bacteria. The major energy supply comes from oxidative phosphorylation reactions and substrates that can be quickly oxidized, such as acetate or TCA-cycle intermediates, cause catabolite repression of glucose catabolism enzymes (MacGregor et al. 1991).

GLUCOSE FERMENTATION BY *ZYMOMONAS*

Bacteria in the genus *Zymomonas* are obligate fermentative bacteria with substrate-level phosphorylation as the only source of energy. They are not, however, strict anaerobes and can grow in the presence of oxygen. The fermentation of glucose produces ethanol, CO_2, and lactic acid as primary products. The pathway of glucose catabolism is unusual in that it is the KDPG route, a pathway with a lower energy yield. The KDPG route is not an efficient route for the fermentation of glucose because only one ATP can be gained per glucose fermented. The pyruvate formed from glucose is oxidized to acetaldehyde and CO_2 by a pyruvate decarboxylase similar to the enzyme common in yeast and the acetaldehyde is directly reduced to ethanol by alcohol dehydrogenase. The pyruvate decarboxylase has an especially efficient promoter and represents about 4 percent of the total cellular protein (Neale et al. 1987). *Zymomonas mobilis* has no TCA cycle and only remnants of a respiratory chain. The KDPG pathway is constitutive and the glucose-6-phosphate dehydrogenase can use either NAD or NADP as the electron acceptor, so reducing power for biosynthetic reactions can be provided.

OTHER BACTERIA

A weak HDP pathway, an active KDPG route, and an active hexose monophosphate pathway characterize the metabolism of bacteria in the genus *Acetobacter*. These bacteria may utilize a hexose cycle with triose phosphate, originating either from the KDPG route or the pentose phosphate route, going to fructose-6-phosphate, glucose-6-phosphate, and 6-phosphogluconate. Bacteria classified as *Gluconobacter* do not possess a complete TCA cycle, a complete HDP pathway, or a KDPG pathway. They can use glucose either by a terminal oxidative route or a pentose phosphate cycle.

Other strictly aerobic bacteria tend to favor the degradation of glucose by the KDPG route and the HDP is rarely used, although some glucose carbon may pass through the pentose phosphate pathway. As examples, bacteria in the genus *Agrobacterium* have been reported to catabolize glucose 55 percent by the KDPG pathway and 44 percent by the pentose route. For bacteria in the genus *Azotobacter* there is no HDP pathway; the pentose pathway is of minor importance but the KDPG route is the major pathway for glucose degradation. Bacteria in the genus *Sphaerotilus* also have been reported to metabolize glucose via the KDPG and pentose phosphate pathways, as have bacteria in the genus *Rhizobium*. For bacteria in the genus *Arthrobacter*, however, an HDP pathway as well as a pentose pathway has been reported. For *Neisseria gonorrhoeae*, about 80–87 percent of glucose goes via the KDPG pathway, while 13–20 percent has been reported to pass through the HMP route.

BIOSYNTHETIC REACTIONS

Small-molecule biosynthesis

AMINO ACIDS

In general, the normal routes of synthesis of amino acids produce the α-oxoacid and a transamination reaction then adds the amino group. The amino acids may be grouped into six families based upon their routes of synthesis (Moat and Foster 1995). Aspartate, threonine, methionine, isoleucine, asparagines, and lysine make up the aspartic acid family, which originates from an intermediate in the TCA cycle, oxaloacetate. Another TCA-cycle intermediate, α-ketoglutarate (α-oxoglutarate), is converted to glutamic acid, glutamine, and arginine. Serine, glycine, and cysteine all require the triose 3-phosphoglycerate in their formation and thus are grouped together. The aromatic acid family comprises phenylalanine, tyrosine, and tryptophan. Erythrose-4-phosphate and phosphoenolpyruvate, both produced during carbohydrate metabolism, are required for the synthesis of the aromatic amino acids. Alanine, valine, and leucine make up the pyruvate family. Alanine is formed directly by transamination of pyruvate, whereas synthesis of valine and leucine requires condensation of two pyruvates to α-acetolactate, which is eventually converted to valine and leucine. Histidine synthesis is independent of the other families and requires ATP and phosphoribosylpyrophosphate.

PURINES AND PYRIMIDINES

The cells must have a supply of phosphorylated ribonucleotides and deoxyribonucleotides for the synthesis of

RNA and DNA. Purines and pyrimidines are synthesized by quite different routes. The purine ring has as its starting material ribose-5-phosphate while the pyrimidine ring originates in aspartate plus carbamoyl phosphate. The pathways of biosynthesis yielding inosine-5′-phosphate (IMP), a critical intermediate in the synthesis of purines, and uridylic acid (UMP), in the pyrimidine pathway, are complex. In bacteria such as *E. coli*, deoxyribonucleoside diphosphates are produced by the reduction of the corresponding ribonucleotide diphosphates in a reaction catalyzed by a ribonucleotide reductase. In a few species of bacteria, vitamin B_{12} is required for the reduction that occurs at the nucleoside triphosphate level. Methylation of the uracil ring to produce thymine occurs at the level of deoxyuridine monophosphatase (dUMP) with methylenetetrahydrofolate usually the donor of the C1 group and the reductant.

FATTY ACIDS AND LIPIDS

Lipids may serve as reserve food materials or as constituents of bacterial membranes. Lipids found in bacteria include phospholipids, lipoproteins, glycolipids, and the lipopolysaccharide of gram-negative bacteria. Most lipids are phospholipids that contain fatty acids ester-linked to glycerol phosphate. Bacteria synthesize fatty acids from acetyl-CoA using an acyl carrier protein (ACP) with a prosthetic group of 4′-phosphopantetheine. Interestingly, synthesis proceeds through the production of a 3-carbon intermediate, malonyl-CoA, produced by the carboxylation of acetyl-CoA. Growth of the fatty-acid chain is achieved by condensation of malonyl-ACP to the extending chain. The newly condensed molecule contains a β-keto group that is removed by reduction of the keto to a hydroxyl; then a dehydration removes the hydroxyl leaving a double bond followed by reduction of the double bond to leave a saturated chain. Synthesis of unsaturated fatty acids from the extended saturated chain can be accomplished in one of two ways. Under anaerobic conditions, the β-hydroxydecanoyl-ACP is acted upon by a special dehydrase to yield a *cis* double bond between carbon atoms 3 and 4. Two-carbon units are added until the proper length is obtained. Under aerobic conditions, molecular oxygen is used to introduce hydroxyl groups, which can be removed by dehydration reactions to produce double bonds.

Degradation of fatty acids is not the reverse of fatty-acid synthesis. Fatty acids are degraded using the β-oxidation pathway. This pathway involves introduction of a double bond into the fatty acid-CoA derivative. A keto group is the introduced β to the carboxyl group by hydration of the double bond and then oxidation of the hydroxyl. The keto group is then attacked by CoA, leading to the production of an acetyl-CoA and leaving the remaining fatty acid-CoA two carbons shorter.

TCA-cycle intermediates as biosynthetic compounds

Bacterial cells need many intermediates for biosynthetic purposes, including 6-carbon sugars for synthesis of cell walls, triose phosphates to make glycerol and lipids, and acetyl-CoA for the synthesis of fatty acids. In aerobic bacteria, the TCA-cycle functions to oxidize acetate and provide energy. However, another major function of the TCA-cycle enzymes is to produce intermediates such as α-ketoglutaric acid and oxaloacetic acid for biosynthetic reactions. During the TCA cycle, one oxaloacetate combines with the acetyl group from an acetyl-CoA to yield citric acid, which is eventually converted back to oxaloacetate and there is no net gain in di- or tricarboxylic acid intermediates. Because some of these intermediates are being used for biosynthetic reactions, mechanisms must exist for their net synthesis. A very important enzyme, especially in enteric bacteria, to replenish oxaloacetate loss as a result of anabolic reactions is phosphoenolpyruvate carboxylase, which forms oxaloacetate from phosphoenolpyruvate and CO_2. The enzyme phosphoenolpyruvate carboxylase is biosynthetic in its regulation and is inhibited by aspartate. Mutants of enteric bacteria that lack the enzyme are unable to grow on a glucose-salts minimal medium unless the medium is supplemented with a compound capable of providing a TCA-cycle intermediate. Pyruvate carboxylase also catalyzes the production of oxaloacetate but uses pyruvate as initial substrate. This enzyme is found in nonenterics such as *B. subtilis* and *Rhizobium etli*. It is also found in eukaryotic organisms.

If the TCA reactions are being used strictly for generation of biosynthetic precursors, oxaloacetate is a key intermediate that is metabolized via two separate pathways. In one pathway oxaloacetate is converted to succinyl-CoA, an essential biosynthetic precursor, by using a reductive TCA pathway. In this pathway malate dehydrogenase and malate dehydrase (fumarase) convert oxaloacetate to fumarate. Then fumarate reductase, instead of the normal TCA cycle enzyme succinate dehydrogenase, reduces the fumarate to form succinate. Succinyl-CoA is formed from succinate using succinate thiokinase. Oxaloacetate and acetyl-CoA can also yield citric acid, which can be converted to α-ketoglutaric acid, another essential precursor, by normal TCA-cycle enzymes. This splitting of the TCA cycle into a reductive and an oxidative branch is common among fermenting bacteria.

Pathways for incorporation of one-carbon compounds into cellular material

Bacteria that can grow on CO_2 as the sole source of carbon are termed autotrophs. However, bacteria that

cannot grow on CO_2 as the sole carbon source also use CO_2 for biosynthesis of cell material; for example, phosphoenolpyruvate carboxylase, which was discussed above, incorporates CO_2 into cellular precursors. Because these reactions are essential for growth under certain conditions, CO_2 is an essential nutrient for most bacteria. However, enzymes like phosphoenolpyruvate carboxylase do not permit growth on CO_2 as the sole carbon source. Autotrophs rely on one of several unique pathways that allow CO_2 to be used as the sole carbon source.

THE CALVIN CYCLE FOR CO_2 FIXATION

The best-studied pathway of CO_2 incorporation for autotrophs is the Calvin cycle. The Calvin cycle, sometimes termed the reductive pentose phosphate pathway, is found in some photosynthetic bacteria and many chemoautotrophs and involves the conversion of a 5-carbon sugar and CO_2 to form two molecules of 3-phosphoglyceric acid. The unique enzymes of the Calvin cycle are phosphoribulokinase, converting ribulose-5-phosphate to ribulose-1,5-bisphosphate, and ribulose bisphosphate carboxylase (sometimes called ribulose-1,5-bisphosphate carboxylase/oxygenase). Ribulose bisphosphate carboxylase converts ribulose bisphosphate and CO_2 to two 3-phosphoglyceric acids. To incorporate the fixed CO_2, the 3-phosphoglyceric acid is phosphorylated, using ATP and phosphoglycerate kinase, to 1,3-diphosphoglyceric acid. This latter compound is reduced by glyceraldehyde-3-phosphate dehydrogenase to glyceraldehyde-3-phosphate, which can be converted to dihydroxyacetone phosphate by triosphosphate isomerase. Aldolase can catalyze the synthesis of fructose-1,6-bisphosphate from the triose phosphates and fructose-1,6-bisphosphate phosphatase can cleave the phosphate from the 1-carbon position to produce fructose-6-phosphate. Enzymatic reactions similar to those of the HMP pathway regenerate the pentose phosphates from hexose phosphates. The final product of these rearrangements is ribulose-5-phosphate, which is converted to ribulose-1,5-bisphosphate by phosphoribulokinase.

THE REDUCTIVE TCA CYCLE FOR CO_2 FIXATION

Bacteria in the genera *Cyanobacteria*, *Rhodospirillaceae*, *Chromatiaceae*, and *Chloroflexaceae* will use the Calvin cycle for CO_2 fixation when growing with CO_2 as the only carbon source. Some bacteria in the genus *Chlorobiaceae*, however, do not possess the enzymes of the Calvin cycle. This family of organisms uses the reductive TCA cycle or the reductive C_4 dicarboxylic acid CO_2 fixation pathway. In this pathway acetyl-CoA is carboxylated by a ferredoxin-dependent pyruvate synthase to form pyruvate. To convert the pyruvate to PEP the enzyme PEP synthetase and ATP are used to form PEP, AMP, and inorganic pyrophosphate. The PEP is carboxylated to oxaloacetate by PEP carboxylase and the normal TCA cycle is reversed, with the oxaloacetate reduced to malate and the malate dehydrated to fumarate. The fumarate is reduced to succinate by fumarate reductase, and the succinate is phosphorylated and changed to succinyl coenzyme A by succinyl-CoA synthetase. The enzyme reaction producing α-ketoglutarate during the normal TCA cycle is irreversible, so a special enzyme is employed during the reductive TCA cycle, an α-ketoglutarate:ferredoxin oxidoreductase. The α-ketoglutarate is changed to citrate by normal enzymes of the TCA cycle, and an ATP-citrate lyase cleaves citrate to form oxaloacetate and acetyl-CoA. Through these reactions, four molecules of CO_2 have been converted to one molecule of oxaloacetate, which can be used for other biosynthetic purposes.

OTHER PATHWAYS FOR INCORPORATION OF ONE-CARBON COMPOUNDS INTO CELLULAR MATERIAL

Methylotrophs are bacteria that can use 1-carbon compounds other than CO_2 as their sole carbon source. Compounds of this type include methane, methanol, formate, and methylamine. When growing on methane it is first converted to methanol by methane monooxygenase (MMO). The methanol is then oxidized to formaldehyde, which can be further oxidized to CO_2 to provide energy or can be converted into cellular material. The MMO exists in either of two forms: a cytoplasmic (soluble) form and a membrane-bound (particulate) form. The soluble form is stable to purification and has been studied in detail. The particulate form is quite labile and little is known about its structure other than that it contains copper.

The incorporation of formaldehyde into cell carbon can proceed by either of two pathways. One pathway is referred to as the serine pathway. This pathway leads to the production of acetyl-CoA from formaldehyde and CO_2. The pathway is known as the serine pathway because the formaldehyde is added to glycine to form serine. This is eventually converted to PEP, which is carboxylated to give oxaloacetate using PEP carboxylase. Through a series of reactions this four-carbon compound is converted into glyoxylate, which is converted to glycine to keep the cycle going, and acetyl-CoA, which can be used for growth.

The other pathway for formaldehyde incorporation is the ribulose monophosphate (RuMP) pathway. In this pathway formaldehyde is added to D-ribulose monophosphate by the enzyme hexulose phosphate synthetase. The product is D-fructose-6-phosphate, which can be converted to other carbohydrates such as glucose-6-phosphate and glyceraldehyde-3-phosphate, or converted back to ribulose-5-phosphate by means of the TK and TA rearrangements. The hexulose phosphate synthetase is specific for D-ribulose-5-phosphate as a substrate but can use other aldehydes, such as glycolaldehyde, in place of formaldehyde (Kato et al. 1988;

Beisswenger and Kula 1991). Most methylotrophs use either the serine or RuMP pathway for incorporation of 1-carbon compounds into cell material.

Methanogens are bacteria capable of producing methane from mainly CO_2 and H_2 (see below). The methane-producing bacteria have the ability to synthesize acetate from 1-carbon compounds. The methyl group of acetate comes from methyltetrahydromethanopterin, which is a folate analog and an intermediate in the reduction of CO_2 to methane. Another molecule of CO_2 is reduced to a bound carbon monoxide by carbon monoxide dehydrogenase and the methane and carbon monoxide are condensed to form acetyl-CoA.

Nitrogen fixation

Many genera of bacteria, including both eubacteria and archaea, are capable of utilizing nitrogen gas (N_2) as the sole source of nitrogen for biosynthetic reactions. The reduction of N_2 to ammonia takes place using an enzyme complex termed nitrogenase. The major nitrogenase of most organisms is a molybdo-iron protein. The active complex has two component proteins, with one termed the iron protein and the other the molybdenum-iron protein (Georgiadis et al. 1992; Chan et al. 1993). The iron protein is a homodimer and the molybdenum-iron protein is a complex with an α-2β-2 structure. The intact complex contains several novel [Fe–S] centers and a novel iron-molybdenum cofactor.

The catalytic reaction involves the iron protein passing an electron to the molybdenum-iron protein, which is the site of nitrogen reduction. This step requires ATP hydrolysis, with a stoichiometry of two ATP per electron transferred. This electron transfer must be repeated six times to reduce the nitrogen to ammonia. The exact mechanism of nitrogen reduction at the iron-molybdenum cofactor remains unclear. In addition to the electrons required for nitrogen reduction there is also obligatory proton reduction during the catalytic cycle, leading to the net consumption of eight electrons per nitrogen reduced. This means that 16 ATP are hydrolyzed per nitrogen reduced.

One of the best studied model organisms for nitrogen fixation is *Azotobacter vinelandii*. This bacterium not only contains the iron-molybdenum nitrogenase but also can synthesize two other nitrogenases. If the growth medium contains molybdenum, then the molybdenum-containing nitrogenase I is synthesized. If the medium is lacking molybdenum but contains vanadium, then nitrogenase 2, which contains an iron-vanadium cofactor in place of the iron-molybdenum cofactor, is produced (Bishop et al. 1982). If the medium does not contain sufficient amounts of either of these two metals, then nitrogenase 3 is synthesized, which contains only iron (Pau et al. 1989). Alternative nitrogenases have also been found in other bacteria.

Nitrogenase activity is normally repressed when other nitrogen compounds are available, and its activity is inhibited by ADP, destroyed by O_2, and repressed by ammonia. In aerobic nitrogen fixers the enzyme must be protected from oxygen. A posttranslational regulation of nitrogenase activity has also been found in many different nitrogen-fixing bacteria (Ludden 1994). It involves the transfer of the ADP-ribose from NAD to the Arg-101 residue of one subunit of the dinitrogenase reductase by the enzyme dinitrogenase reductase ADP-ribosyltransferase (DRAT). This group can be removed by another enzyme, dinitrogenase reductase-activating glycohydrolase (DRAG), which restores nitrogenase activity.

RESPIRATION

Aerobic respiration

Aerobic respiration is the condition when oxygen is the final electron acceptor of catabolism. In bacteria that can utilize aerobic respiration, the presence of oxygen will result in the repression of any fermentation pathways or anaerobic respiration pathways. A number of different electron carriers are involved in bacterial respiration, including NAD and NADP, flavoproteins, quinones, [Fe-S] proteins, and cytochromes. Flavoproteins are oxidation/reduction enzymes that contain flavin adenine mononucleotide (FMN) or flavin adenine dinucleotide (FAD). Flavins are synthesized from riboflavin and, upon reduction, transport two protons and two electrons. The actual redox potential of the oxidation/reduction reaction of flavoproteins can vary depending upon the protein group, although a range of 0.0–0.2 V is normal. Quinones are hydrophobic electron carriers that can shuttle electrons and protons through the lipid bilayer. The two most common quinones are ubiquinone (coenzyme Q) and menaquinone (vitamin K or MK). Proteins containing non-heme iron- and sulfur-containing clusters, referred to as iron-sulfur proteins, are components of almost all respiratory chains. Some well-studied iron-sulfur proteins are ferredoxin, rubredoxin, and a high-potential iron protein (HiPIP). These [Fe-S] centers carry only one electron and with midpoint potentials ranging from -0.40 to $+0.35$ V can be involved throughout the respiratory chain. Cytochromes are redox proteins that contain heme and transport a single electron. Cytochromes have characteristic light-absorption bands in the visible range and are categorized on the basis of their absorption characteristics. One type of cytochrome, the *c*-type, is additionally distinguished because the heme is covalently attached to the protein by thioether linkages.

The standard mitochondrial respiratory chain serves as a useful model because it was originally derived from the bacterial respiratory chain. The chain is divided into

four protein complexes, complexes I–IV, and additional components required to shuttle electrons. All of the components discussed below are found in bacteria. The major difference between bacterial and mitochondrial electron transport chains is that the bacterial respiratory complexes have a simpler subunit structure.

Complex I is the NADH-ubiquinone oxidoreductase, which oxidizes reduced NADH and transfers electrons to ubiquinone. This complex is made up of at least 20 different polypeptides and contains iron-sulfur proteins and flavoproteins. Electrons passed to the quinone along with two protons convert the quinone to quinol. This can then diffuse to other electron acceptors such as complex III. Complex III is also called the bc_1 complex or the ubiquinol-cytochrome *c* oxidoreductase. In bacteria this complex is made of three major subunits. Electron flow through the bc_1 complex is complex, with the two electrons from quinol eventually flowing to two different acceptors. This flow has been termed the Q cycle. Data from studies of the high-resolution structure of the bc_1 complex have suggested movement of the polypeptides during electron flow is critical for determining the eventual oxidant (Zhang et al. 1998). One of the terminal oxidants in the Q-cycle is a soluble cytochrome *c*. This cytochrome *c* can readily diffuse between different donors and acceptors to facilitate electron flow during respiration. Cytochrome *c* serves as a reductant for complex IV, also termed the cytochrome *c* oxidase, which reduces oxygen to water. This protein is a heme-copper protein whose structure has been solved (Iwata et al. 1995; Yoshikawa et al. 1998). A hallmark of this type of oxidase is the presence of a heme and copper in close proximity resulting in a structure termed a binuclear center. This is the site of oxygen reduction. Cytochrome *c* oxidase is also a vectorial proton pump with residues in and around the binuclear center critical for gating proton flow during turnover. Complex II is succinate dehydrogenase, also termed the succinate-ubiquinone oxidoreductase. This complex serves as an alternative site for entry of electrons into the respiratory chain.

Unlike mitochondria, bacteria can differ greatly in the composition of their respiratory chains. Even in individual bacteria, respiratory chains vary as a function of changes in growth conditions; for example, *E. coli* modulates the beginning and end of its aerobic respiratory pathway depending on available oxygen levels (Gennis and Stewart 1996). *E. coli* has two NADH dehydrogenases. The type I NADH dehydrogenase is the bacterial equivalent of the mitochondrial Complex I. The type II NADH dehydrogenase is a single subunit enzyme. It is a flavoprotein that contains one noncovalently bound FAD per polypeptide chain and also contains [Fe-S] centers. The type II oxidase is primarily expressed when oxygen is not limiting. There are also two terminal oxidases in *E. coli*. With higher levels of oxygen present, a cytochrome *o* oxidase is expressed. This oxidase, which uses quinol as reductant, is a member of the same family of oxidases as the mitochondrial oxidase and contains a heme-copper binuclear center. Under microaerophilic conditions, however, the cytochrome *d* oxidase is expressed. This terminal oxidase is only found in bacteria. This protein contains the novel *d* heme and has an extremely high affinity for oxygen.

Other bacteria have respiratory chains almost exactly like that found in mitochondria. Probably the best studied example is found in bacterium *Paracoccus denitrificans* (Baker et al. 1998). Bacteria also have the capacity to use many compounds as reductants. Compounds ranging from methanol to iron can be used as electron donors and thus would require their own associated oxidoreductase.

Oxidative phosphorylation

It has been known for many years that aerobes gain ATP from the transport of electrons in the cell membrane, a phenomenon called oxidative phosphorylation. During respiration, oxidation/reduction reactions take place in the membrane of the cells so that an electrochemical potential (δp) or proton-motive force (pmf) is created with protons on the exterior side of the membrane. Because the respiratory chain consists of hydrogen carriers and electron carriers in alternating sequences across the cytoplasmic membrane and because the cell membrane was impermeable to OH^- and H^+, as oxidation reactions transferred protons from one side of the membrane to the other, a pH gradient and an electrical potential was established across the membrane (Mitchell 1961). The electrochemical gradient that occurs as a consequence of electron flow through the respiratory chain can be used to make ATP, drive solute transport, drive the rotation of the flagellum, and drive unfavorable electron-transport reactions.

Respiration-dependent ATP synthesis is carried out by the ATP synthase, also termed the F_1F_0 type ATPase. The ATPase is a complex multiprotein system and has been compared to a small organelle. When protons pass from the outside to the inside of the membrane, their passage through the ATP synthase causes inorganic phosphate to be esterified and ADP is converted to ATP.

ATP synthase can be dissociated into two complexes termed the F_0 and F_1. The structure named F_1 contains five different subunits with a ratio of $\alpha 3$, $\beta 3$, γ, δ, and ϵ. The F_1 contains six ATP binding sites, one each on the α and β subunits. However, only those on the β subunits are capable of ATP synthesis. By itself the F_1 complex functions as an ATPase, hydrolyzing ATP to ADP and Pi. The F_0 complex usually consists of three different subunits in bacteria with a stoichiometry of a, b2, and c10–12. The F_0 is an integral membrane complex that

acts as an H^+ channel to translocate H^+ across the cytoplasmic membrane. Using purified protein it has been demonstrated that the complex functions as a rotary motor (Sambongi et al. 1999). The rotor is made up of the c subunits of the F_0 along with the γ and ϵ subunits of the F_1 complex. The remaining proteins are proposed to act as a stator. Models of ATP synthesis require that proton flow through the F_0 causes the rotor to turn. This drives rotation of the γ subunit and as it turns it causes structural changes in the ATP binding sites on the β subunits. The structural changes in the β subunits cause them to switch through low-, medium-, and high-affinity nucleotide binding sites. These shifts lead to the synthesis of ATP. High-resolution structures of both the F_1 and F_0 complexes have been determined and are generally consistent with models of ATPase function (Abrahams and Leslie 1994; Stock et al. 1999).

All bacteria, even strict anaerobes, must maintain an electrochemical gradient of protons across the membrane of the cell. This is needed to support the integrity of the cell membrane, to provide energy for motility, and to transport nutrients into the cell. Under anaerobic conditions, the F_1F_0 complex can function in the reverse direction, hydrolyzing ATP by means of an ATP hydrolase associated with the cell membrane to generate an electrochemical gradient. Some fermenting bacteria are also able to use the excretion of fermentation products through the cell membrane to generate a proton gradient.

In some bacteria, Na^+ substitutes for H^+ as the coupling ion and ATP-driven Na^+ pumps have been described in several genera. All cells appear to transfer energy obtained from external sources to energy stored as either ATP, proton-, or sodium-motive force. These energy sources may be interconvertible and it appears that any one can satisfy all of the energy sources of the cell (Skulachev 1994). An example of a Na^+-dependent respiratory chain was mentioned above in the discussion of oxaloacetate oxidation by *P. modestum*.

Oxygen toxicity

Cells growing in the presence of molecular oxygen produce some very reactive and toxic oxygen species, such as the superoxide radical, the hydroxyl radical, and hydrogen peroxide. These compounds are produced by autooxidation of components of the electron transport chain. In particular, flavoproteins have been shown to produce reactive oxygen species (Messner and Imlay 1999). In order to protect themselves against such compounds, bacteria have evolved special enzymes. Superoxide dismutase (SOD) converts the toxic superoxide anion (O_2^-) to hydrogen peroxide. *E. coli* is known to possess three species of SOD: Mn-SOD, Fe-SOD, and a periplasmic Cu, Zn-SOD (Benov and Fridovich 1994). Catalase and a class of enzymes named peroxidases destroy hydrogen peroxide. Catalase converts hydrogen peroxide to O_2 and water. The synthesis of catalase is normally regulated and the level of activity kept low until needed. *E. coli* encodes two different catalases, hydroperoxidase I and hydroperoxidase II.

E. coli has been an informative model system for the study of how cells respond to oxidative stress. There are several regulons that control the synthesis of proteins responsible for mitigating toxic effects of oxygen radicals in *E. coli*. The two best-studied regulators are the SoxR and OxyR proteins. SoxR responds to increases in superoxide. When activated the SoxR protein activates transcription of SoxS, which activates transcription of target genes in the regulon. SoxR is activated by oxidation of a reduced [2Fe-2S] center in the protein (Hidalgo et al. 1997). It is unclear what molecule oxidizes SoxR but superoxide is a likely candidate. OxyR responds to increases in hydrogen peroxide. It is activated by the formation of a disulfide bond upon exposure to hydrogen peroxide (Zheng et al. 1998). Another important regulator of expression of oxygen-radical tolerance factors is the sigma factor (σ^s), which is synthesized at high levels during stationary phase growth and may control as many as 50 genes.

While the reactivity of the oxygen radicals allows them to react with many different cellular components, there have been a few especially sensitive targets identified. In *E. coli* lacking superoxide dismutase, cellular injury has been determined mainly to occur to a set of dehydrase enzymes (Storz and Imlay 1999). The common factor among this class of enzymes is that they contain superoxide-sensitive [Fe-S] centers. The precise targets of hydrogen peroxide accumulation have not been identified.

Anaerobic respiration

NITRATE RESPIRATION

As mentioned previously, fermentation is the condition in which the final electron is an organic compound. In aerobic respiration, oxygen is the final electron acceptor. Anaerobic respiration is the situation where the final electron acceptor is a compound other than oxygen. There are many compounds that can serve as alternative electron acceptors. One of the most heavily studied is nitrate. Nitrate reduction can proceed via two pathways (Berks et al. 1995). One pathway is the reduction of nitrate to ammonia, termed 'ammonification.' The other pathway is the reduction of nitrate to nitrogen gas, termed 'denitrification.' Both of these pathways allow growth in the absence of oxygen and are termed 'dissimilatory pathways.' Nitrate can also be reduced to ammonia for biosynthetic purposes in an assimilatory pathway. However, the biosynthetic enzyme pathway is not coupled to ATP formation.

Pathways of nitrate reduction

Bacteria that can use nitrate as a terminal electron acceptor for energy production normally will not do so in the presence of oxygen, because aerobic respiration can yield more energy. Possible electron donors for nitrate reduction include NADH formed from a variety of catabolic pathways, formate, H_2, glycerol-3-phosphate, succinate, and lactate. The electron flow is from NAD, through flavoproteins, to cytochromes, and finally to nitrate.

The first step in nitrate reduction is the reduction of nitrate to nitrite. There are two types of dissimilatory nitrate reductases. The enzyme typically associated with nitrate respiration is a membrane-bound three-subunit complex, although the membrane-anchoring subunit (γ or NarI) is sometimes lost during purification (Moreno-Vivian et al. 1999). The largest of the three subunits (α or NarG) contains molybdenum bound by the cofactor molybdopterin guanine dinucleotide and a [4Fe-4S] center. The remaining subunit (β or NarH) contains several [4Fe-4S] centers and a [3Fe-4S] center. The membrane-anchoring subunit typically contains a *b*-type heme. The other type of nitrate reductase is a periplasmically located enzyme. The periplasmic nitrate reductase is a heterodimer with prosthetic groups similar to those found in the membrane-bound nitrate reductase.

The ammonification and denitrification pathways diverge at the level of nitrite. During ammonification a single enzyme catalyzes the six-electron reduction of nitrite to ammonia. In *E. coli* and other enteric bacteria this enzyme is a periplasmically located *c*-type cytochrome (Gennis and Stewart 1996). Ammonia is the terminal product of ammonification so no other enzymes are involved. In denitrifiers, nitrite is reduced to nitric oxide, a gaseous nitrogen oxide (Zumft 1997). There are two types of nitric-oxide-producing nitrite reductases. One contains copper as its redox-active metal and the other contains heme. Both are periplasmically located. Nitric oxide is reduced to nitrous oxide by a membrane-bound nitric oxide reductase containing heme and non-heme iron. Interestingly, this protein is related to the family of proteins that includes the heme-copper binuclear center containing oxygen-reducing oxidases. Nitrous oxide is reduced to nitrogen gas by a copper-containing, periplasmically located enzyme. This enzyme is also related to the terminal oxygen-reducing oxidases.

Dissimilatory nitrate reduction is widespread amongst the bacteria. Ammonification is best studied in the enteric bacteria but is found in other bacteria, for example *B. subtilis* (Nakano and Zuber 1998). Denitrification occurs in both eubacteria and archaea. Ongoing sequencing projects have found portions of the denitrification electron transport chain in several pathogens including *Neisseria meningitidis*, *N. gonorrhea*, and *Corynebacterium diphtheriae*. The role of dissimilatory nitrate reduction in these pathogens has not been determined.

REGULATION OF NITRATE REDUCTION IN *E. COLI*

In *E. coli* several signals are required for the cells to activate expression of enzymes required for the reduction of nitrate. First, oxygen concentrations must be limiting because oxygen is always a preferred oxidant. Low oxygen activates the transcriptional regulatory protein Fnr. Fnr contains an oxygen sensitive [Fe-S] center that undergoes changes in structure in the presence of oxygen (Khoroshilova et al. 1997). Nitrate and nitrite are sensed by 2, 2-component regulatory systems. The interaction of these two systems and their target proteins is complex and is used to activate expression of some genes, such as those encoding nitrate and nitrite reductase, while at the same time repressing expression of other genes (Darwin et al. 1997).

Sulfate reduction

Another commonly used terminal oxidant is sulfate. Dissimilatory sulfate reducers are heterotrophs that are almost always strict anaerobes. Sulfate-reducing bacteria are found in both the eubacteria and archaea. The best studied sulfate reducers belong to the genus *Desulfovibrio*. The first step in the use of sulfur as electron acceptor is its activation on an AMP molecule. The enzyme adenyltransferase (ATP-sulfurylase) uses ATP and sulfate as substrates to form adenyl sulfate (APS) and inorganic pyrophosphate (Hansen 1994). The pyrophosphate is hydrolyzed by inorganic pyrophosphatase with the energy in the pyrophosphate bond lost to the cells. The enzyme APS reductase adds two electrons to APS to reduce the sulfate to sulfite with the liberation of AMP. Next, sulfite reductase reduces sulfite to form sulfide (S_2). A proton-motive force is generated by the appropriate topological arrangement of proton-producing and proton-consuming reactions on either side of the cytoplasmic membrane.

Desulfovibrio desulfuricans is a strict anaerobe that can ferment glucose and pyruvate and can also grow using lactate if sulfate is present to serve as an electron acceptor. Pyruvate, formed by either the HDP pathway or lactate oxidation, is cleaved by pyruvate/ferredoxin oxidoreductase, yielding CO_2, H_2, and acetyl-CoA. The acetyl-CoA can be converted to acetyl-phosphate and then acetate with ATP formation. *Desulfovibrio desulfuricans* can also grow using CO_2, H_2, and acetate if sulfate is present. In this case, electrons are transferred from H_2 to sulfate to gain energy and the pyruvate/ferredoxin oxidoreductase reaction is reversed to make pyruvate for biosynthetic reactions.

Additional terminal electron acceptors

Alternative terminal electron acceptors are not limited to inorganic oxides. Oxidized metals such as iron or manganese can be used as terminal oxidants; for example, members of the genus *Shewanella* can utilize both iron and manganese as terminal electron acceptors (Myers and Nealson 1990). Many carbon compounds can serve as terminal oxidants; examples include dimethyl sulfoxide, trimethylamine oxide, and fumarate. The crystal structure of the membrane-bound fumarate reductase from the microaerophile *Wolinella succinogenes* has been determined (Lancaster et al. 1999). It has also been demonstrated that halocarbons can serve as electron acceptors. Molecular studies of the halorespiring bacterium *Desulfitobacterium dehalogenans* are starting to identify components required for this form of anaerobic growth (Smidt et al. 1999). Some bacteria appear only to be capable of halorespiration (Maymo-Gatell et al. 1997). Another notable carbon compound that appears to serve as a terminal electron acceptor is humic acid (Lovley et al. 1996).

Additional electron donors

In addition to the capacity to utilize a wide variety of compounds as terminal electron acceptors, bacteria also have the capacity to utilize many compounds as electron donors for respiration. In addition to the wide variety of organic compounds that can be used, many inorganic compounds can be used as electron donors. Ammonia and nitrite can be oxidized by a group of bacteria collectively known as nitrifiers. Ammonia oxidizers, such as members of the genus *Nitrosomonas*, can oxidize ammonia to nitrite via the intermediate hydroxylamine (Hooper et al. 1997). Ammonia oxidizers cannot further oxidize nitrite. Nitrite oxidizers, such as members of the genus *Nitrobacter*, oxidize nitrite to nitrate but cannot oxidize ammonia. Reduced sulfur compounds can also be oxidized to provide electrons for respiration. Sulfate oxidation has been heavily studied in the genus *Thiobacillus* (Kelly et al. 1997). Some thiobacilli can couple sulfur oxidation to nitrate reduction, completely eliminating involvement of carbon oxidation or reduction in respiration. This type of metabolism is referred to as 'lithotrophy' and can be found in many other bacterial genera. Other potential reductants include iron, manganese, H_2, and carbon monoxide.

BACTERIAL PHOTOSYNTHESIS

Photosynthesis is the conversion of the energy available in light to chemical energy, which is available for cell growth. Many bacteria are capable of photosynthesis and there are several different bacterial photosynthetic electron-transport systems. In all of these systems light is absorbed (harvested) by accessory pigments and the energy transferred to a reaction center. The reaction center carries out the charge separation that permits light energy to be converted to chemical energy. The different electron-transport systems can be differentiated into three groups based on the types of bacteria having a particular system. The three types of bacteria are:

1. purple photosynthetic bacteria
2. green sulfur photosynthetic bacteria
3. cyanobacteria.

A brief description of the photosynthetic electron-transport chain of each group is presented below.

Purple photosynthetic bacteria

In the purple photosynthetic bacteria both organic and inorganic compounds, such as reduced-sulfur compounds, can be used as electron donors. However, some bacteria are limited in their choice of electron donor. Photosynthesis in the purple bacteria, as is true for most bacteria, is an anaerobic process. Therefore, expression of the components required for photosynthesis occurs when oxygen is limiting. Oxygen limitation causes the most significant increase in photosynthetic gene expression with light having a much smaller effect (Buggy et al. 1994).

Light absorption is carried out by a group of protein-associated pigments organized into light-harvesting (LH) complexes. In most bacteria there are two complexes, referred to as LHI and LHII. High-resolution and modeling studies of LHI and LHII have shown that both are roughly circular and contain both bacteriochlorophyll and carotenoids (Hu et al. 1998). Carotenoids absorb at lower wavelengths, in the 500-nm range, while the bacteriochlorophylls absorb at higher wavelengths (800–900 nm). Current models of the organization of LHII and LHI have many LHII complexes surrounding the LHI complex, which has the reaction center at its center. Therefore, the probable direction of excitation transfer about light absorption is LHII to LHII and LHI and then LHI to the reaction center.

Transfer of excitation energy to the reaction center causes the potential of an electron located at a dimer of bacteriochlorophylls, known as the special pair, to become excited to a lower reduction potential. This electron is then transferred through the electron-transfer components of the reaction center and eventually resides on a quinone molecule designated UQ_A. This quinone is tightly bound to the reaction center complex. UQ_A then transfers the electron to a second quinone referred to as UQ_B. This quinone is less tightly bound and, when fully reduced, can diffuse away from the reaction center complex. These steps are then repeated to reduce the quinone fully, which, after binding two protons, diffuses into the lipid bilayer. Because the special pair is located on the periplasmic surface and the

ubiquinones are located on the cytoplasmic surface, electron transfer is vectorial. This vectorial transfer of electrons is referred to as charge separation because a negative charge is moved to the cytoplasmic side and a positive charge is left on the periplasmic side of the membrane. The details of electron flow through the reaction center are well defined because the high-resolution structure of the reaction center from purple photosynthetic bacteria has been solved (Deisenhofer et al. 1995).

Once UQ_B diffuses into the lipid bilayer it can pass its electrons to the bc_1 complex. Electron transfer through the bc_1 complex leads to the generation of a proton-motive force that can be used for the synthesis of ATP. The electrons are then passed to a periplasmic cytochrome *c* that then passes the electrons back to the reaction center. This type of electron flow during photosynthesis is termed 'cyclic photosynthesis.' Some photosynthetic bacteria use electron donors with reduction potentials higher than the NAD^+/NADH couple so these cells use the proton-motive force to drive reverse electron transport to generate NADH.

Green sulfur bacteria

The basic mechanisms of light harvesting and electron flow through the reaction center are the same in both purple photosynthetic and green sulfur bacteria. The reaction center of the green sulfur also contains a special pair whose reduction potential is decreased upon transfer of excitation energy. The reaction center differs in the nature of its associated cofactors. The green sulfur bacteria reaction center includes iron-sulfur centers, which are not present in the reaction center of the purple photosynthetic bacteria (Oh-oka et al. 1995). In addition, the potential of the excited electron in the reaction center of the green sulfur bacteria is low enough to reduce NAD^+ to NADH. This allows electron transfer to be noncyclic. However, cyclic electron transfer can occur, generating a proton-motive force and ATP production. Sulfide is a common electron donor for the green sulfur bacteria. Its electrons are fed into the electron-transport chain via periplasmic cytochromes.

Cyanobacteria

Cyanobacteria differ from the other photosynthetic bacteria by using water as the source of electrons for photosynthesis. Another difference is that the photosynthetic electron-transport chain of the cyanobacteria is essentially a combination of the purple and green photosynthetic electron-transport chains. The electron-transport chain in cyanobacteria is differentiated into reaction center II (RCII), which is related to the reaction center from purple photosynthetic bacteria, and reaction center I (RCI), which is related to the green sulfur bacteria reaction center. Electrons from water first flow through RCII, allowing formation of a proton-motive force. Electrons then flow to RCI via a copper protein called plastocyanin. The electron is then transferred to $NADP^+$ for biosynthetic purposes or back to RCI generating a proton-motive force. A continual supply of electrons is required because flow through RCII is not cyclic. This is generated by the manganese-containing water-splitting apparatus. The photosynthetic electron-transport pathway of plant chloroplasts is very similar to that of the cyanobacteria.

METABOLISM AMONG THE ARCHAEBACTERIA

Archaebacteria (domain archaea) encompass a diverse array of physiological processes. Probably the most prominent archaea are the methanogens. These bacteria grow by converting a limited set of substrates to methane. In addition to methanogens other archaea carry out aerobic or anaerobic respiration. No photosynthetic archaea have been isolated. However, some halophilic archaea can use light energy to generate a proton-motive force but this reaction is distinct from photosynthesis.

Methanogenesis

All known methanogens are members of the domain archaea and represent the largest group in that domain, with thermophiles, mesophiles, and halophiles included in the group. Methanogens are obligate anaerobes that reduce CO_2 and a few other substrates, such as formate, methanol, methylamines, or acetate, to produce the most reduced organic compound, methane. Most methanogens are autotrophs and the reduction of CO_2 is their only energy-yielding pathway.

The first step of methanogenesis is catalyzed by either a tungsten- or molybdenum-containing formyl-methanofuran dehydrogenase (Thauer 1998). CO_2 is activated and reduced to the level of formyl on methanofuran. The carbon is then transferred to the cofactor tetrahydromethanopterin. The carbon is reduced from the formyl to the methyl state while attached to this cofactor. At this stage the methyl is transferred to the cofactor coenzyme M. Methyl-coenzyme M (methyl-CoM) is reduced by methyl-CoM reductase to methane. The methyl-CoM reductase contains the unusual nickel tetrapyrrole, F_{430}. Methyl reduction also requires cofactor B (7-mercaptoheptanoylthreonine phosphate). During the reaction the cofactors coenzyme M and coenzyme B become linked via a disulfide bond. This bond is cleaved using the membrane-bound enzyme heterodisulfide reductase.

During methanogenesis from methanol about one out of four methanols are oxidized, by reversing part of the

methanogenesis pathway, to provide electrons for the reduction of methanol to methane. Methanogenesis from acetate is more complex, requiring that acetate be first converted to acetyl-CoA using either the combination of acetate kinase and phosphotransacetylase or acetyl-CoA synthetase (Ferry 1999). Carbon monoxide dehydrogenase then breaks the carbon–carbon bond forming a carbonyl and a methyl group. The carbonyl is oxidized to CO_2 and the electrons used to reduce the methyl group to methane.

The energetics of methanogenesis are not completely understood. It seems likely that the heterodisulfide reductase step permits formation of a proton-motive force (Deppenmeier et al. 1991). The coenzyme M–coenzyme B disulfide serves as the terminal electron acceptor, with H_2 being a likely electron donor. It is not clear how the proton-motive force is generated during this reduction but it is possible that scalar production of protons by the hydrogenase is the source. Methanogens do contain ATPases similar in structure and organization to that of the F_1F_0-type ATPases, which are designated A_1A_0-type ATPases (A meaning 'archaeal' here). While there is no direct evidence indicating that the ATPases are ATP synthases, it seems likely they are used for that purpose. The transfer of carbon from tetrahydromethanopterin to coenzyme M may also be an energy-coupling step.

Methanogens must synthesize all cellular organic compounds from simple starting material and some methanogens can grow on a completely minimal medium and convert CO_2 to all required organic material. During growth with CO_2 as the carbon source it is incorporated into acetyl-CoA. This reaction utilizes the carbon monoxide dehydrogenase discussed above. One unit of CO_2 is bound to the carbon monoxide dehydrogenase and then oxidized to carbon monoxide. A second CO_2 unit is then reduced to a methyl group using the same reactions occurring during methanogenesis. The methyl group is then passed to carbon monoxide dehydrogenase where it is combined with the bound carbon monoxide. The dehydrogenase then catalyzes the production of acetyl-CoA. The acetyl-CoA is next converted to phosphoenolpyruvate, which is probably converted to further primary precursors by a modified reductive TCA cycle.

Methanogens such as *Methanobacterium* and *Methanosarcina* assimilate CO_2 but have an incomplete TCA cycle. In *Methanobacterium*, succinate is apparently converted to succinyl coenzyme A and then to α-ketoglutarate. In *Methanosarcina*, oxaloacetate appears to be converted to citrate, which is converted to isocitrate and then to α-ketoglutarate. Although glucose is not a carbon or energy source for growth, there are some reports of methanogens taking up and metabolizing glucose and the distribution of radioactive label that suggested the presence of the HDP pathway. However, there is no report of the presence of phosphofructokinase, a key enzyme of the catabolic HDP pathway.

Nonmethanogenic archaea

The nonmethanogenic archaea are a diverse mix of organisms that include thermophiles, acidophiles, strict aerobes, strict anaerobes, and facultative bacteria. Representatives of many of these groups have been studied in some detail and genome-sequencing efforts are also contributing to our understanding of these bacteria. Strict aerobes are somewhat rare, reflecting the preference of archaea for anaerobic growth. One obligately aerobic genus studied in some detail is the genus *Sulfolobus*. These bacteria are thermophilic acidophiles, some of which can use organic compounds as electron donors, while others use reduced sulfur compounds. The respiratory components have been characterized from some *Sulfolobus* species. These characterizations have shown that the respiratory complexes are orthologs of the eubacterial complexes; however, in many cases they are quite divergent. A good example is provided by the SoxABCD quinol oxidase from the bacterium *Sulfolobus acidocaldarius* (Lubben et al. 1992). Sequence analysis indicated that this complex contains a subunit with a heme-copper binuclear center and other components of binuclear center-containing quinol oxidases. However, in addition to those proteins it has a b-heme-containing protein that is similar to the b-heme-containing protein of the bc_1 complex. This suggests that the complex III and IV components have been modified into a single active complex. The observation that respiratory proteins in eubacteria and archaea are orthologs but that there are no photosynthetic archaea has led some to suggest that respiration arose before photosynthesis and that the archaea and eubacteria diverged before photosynthesis.

The aerobic respiratory chain of halophilic archaea has not been studied as extensively as that of the *Sulfolobus* strains. However, data suggest that the proteins are orthologs of other known respiratory proteins. Some halophilic archaea have been shown to use alternative electron acceptors such as nitrate and fumarate. Several halophilic archaea also have the capacity to use light energy for energy conservation. A single protein termed bacteriorhodopsin carries out this process. Bacteriorhodopsin occurs in high concentration in the membrane and the occurrence of these purple membranes in certain halophiles led to the interest in this protein. The structure and catalytic mechanism of bacteriorhodopsin has been studied in great detail. It is a 26-kDa integral membrane protein with seven transmembrane helices (Pebay-Peyroula et al. 1997). It contains the chromophore retinal covalently attached to the protein at a lysine in one of the transmembrane helices. The absorption of light shifts the *trans*-retinal to

cis-retinal. This structural change begins a reaction scheme that ejects a proton into the periplasmic surface and causes the uptake of a proton from the cytoplasmic side of the membrane. Mutagenesis of bacteriorhodopsin has identified several acidic residues that make up the proton channel. In addition to bacteriorhodopsin these halophiles have several other retinal-containing proteins. One of these, halorhodopsin, is an internally directed chloride pump. The other two are photoreceptors involved in phototaxis.

Many of the nonmethanogenic archaea use proteins and amino acids as carbon and energy sources but a few have been shown to use carbohydrates. *Halobacterium saccharovorum* has been shown to possess a modified KDPG (Entner/Douderoff) pathway (compare with Figure 10, p. 59) where unphosphorylated glucose is oxidized to gluconate by a NAD-dependent dehydrogenase and a gluconate dehydrogenase converts the gluconate into 2-keto-3-deoxygluconate. Next, a kinase, using ATP as the phosphate source, phosphorylates the 2-keto-3-deoxygluconate to form KDPG. KDPG aldolase cleaves this to form glyceraldehyde-3-phosphate and pyruvate as in the normal KDPG pathway, and glyceraldehyde-3-phosphate is converted to pyruvate by the usual HDP pathway enzymes. Pyruvate is converted to acetyl-CoA using pyruvate/ferredoxin oxidoreductase.

Thermoacidophilic archaebacteria such as *Sulfolobus solfataricus* and *Thermoplasma acidophilum* have no phosphofructokinase and, therefore, no HDP pathway. Instead, they have been shown to use another variation of the KDPG pathway, a completely non-phosphorylated pathway. Glucose is oxidized to gluconic acid, which is dehydrated to 2-keto-3-deoxygluconate. This is cleaved by an aldolase to yield pyruvate and glyceraldehyde. The glyceraldehyde is oxidized to glyceric acid, which is phosphorylated to 2-phosphoglyceric acid and converted to phosphoenolpyruvate. The latter compound is cleaved by pyruvate/ferredoxin oxidoreductase. There is no evidence for acetyl phosphate formation as a precursor to acetyl-CoA formation (Danson 1988).

REGULATION OF PHYSIOLOGICAL PROCESSES

Operon organization and expression

Perhaps the best example of operon organization and expression is provided by the set of genes required for lactose metabolism. In order to grow using the disaccharide lactose as a carbon and energy source, *E. coli* requires the presence of the enzyme β-galactosidase (once termed lactase) to cleave lactose into the monosaccharides, D-glucose and D-galactose. This enzyme is inducible, meaning that without the presence of lactose in the growth medium, there is only a very low basal or endogenous level of the enzyme in the cells. However, within minutes of addition of lactose to the medium the differential rate of synthesis of the enzyme, which is the rate of enzyme synthesis compared with the rate of total cell protein synthesis, increases until the amount of enzyme in the cells is 10 000 times higher than previously. If the lactose is removed from the medium, the rate of β-galactosidase synthesis decreases to the previous basal level while at the same time the concentration of enzyme in the cell is diluted by the synthesis of new proteins during cell growth. When cells are provided with lactose, several proteins are induced at the same time, a phenomenon known as coordinate induction. These proteins include β-galactosidase, lactose permease (the protein responsible for the transport of lactose through the cell membrane), and a protein catalyzing the acetylation of certain disaccharides.

During studies on lactose catabolism by *E. coli*, mutants were obtained that changed the regulation of these three enzymes such that they were produced at high levels in the absence of lactose. These mutants where termed constitutive mutants and, because a single mutation affected the regulation of all three proteins at once, the expression of the genes coding for those proteins had to be under the control of a common regulatory gene. Such enzymes are said to be coordinately controlled. The analysis of structural gene and regulatory gene mutations that effected lactose catabolism in *E. coli* led Jacob and Monod (1961) to postulate the operon model of gene regulation. This model proposed that a single regulator controlled expression of all three genes because the genes are cotranscribed on a single transcript. An operon is a region of DNA containing cotranscribed genes and control sequences.

Further studies provided evidence that the regulatory gene produced a product that normally blocked the formation of the enzymes involved in lactose catabolism. This product was termed the repressor. When the lactose operon was induced, an RNA polymerase would bind to the DNA at a site named the promoter region. In the absence of the inducer, however, the repressor protein bound to a DNA site named the operator region and prevented transcription by the RNA polymerase. Thus, the regulation was a negative control system in that the normal function of the regulator gene was to prevent the formation of mRNA for the operon. Any mutation resulting in the loss of function of the repressor (the product of the *lacI* gene) would result in the loss of repression and the constitutive expression of the enzymes of the lactose operon (Jacob and Monod 1961).

THE LACTOSE OPERON OF *E. COLI*

The arrangement of the genes of the lactose operon of *E. coli* is shown in Figure 11. The order of the three

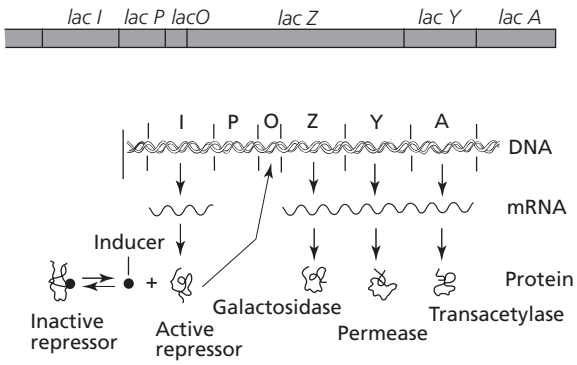

Figure 11 *The lactose operon of* Escherichia coli

structural genes of the *lac* operon is *lacZ*, *lacY*, and *lacA*, encoding β-galactosidase, lactose permease, and thiogalactoside transacetylase, respectively. The promoter (*lacP*) and operator (*lacO*) regions are adjacent to the *lacZ* gene and actually overlap. The regulatory gene (*lacI*) is situated next to the operon. The regulatory gene (*lacI*) is the structural gene for a protein that is termed the lactose repressor. The lactose repressor is an allosteric protein that is normally expressed constitutively and is a DNA-binding protein. When bound to the operator region the repressor blocks binding of RNA polymerase and blocks transcription of the operon. The repressor contains a binding site for the inducer of the lactose operon. The inducer serves as a negative effector and, when bound to the repressor, it decreases the affinity of the repressor for DNA. With the removal of the repressor from the operator region, RNA polymerase can transcribe the operon. The actual inducer molecule is not lactose but an isomer of lactose, allolactose, which is a disaccharide formed by a side reaction of β-galactosidase. Lactose is a D-glucose-D-galactose dimer with a β-1,4 linkage, whereas allolactose differs from this in that it possesses a β-1,6 linkage.

The purpose of the thiogalactoside transacetylase, coded by the *lacA* gene, remained a mystery for a number of years. This enzyme is now believed to be associated with the lactose operon for purposes of detoxification. The enzyme possesses the ability to acetylate a variety of different disaccharides, but lactose is one of the poorest substrates. The lactose permease is able to transport a number of disaccharides other than lactose into the cell and if these disaccharides cannot be further metabolized they accumulate and may be toxic for cell growth. Upon acetylation of these disaccharides by the thiogalactoside transacetylase, they are rapidly excreted by the cells and not transported back into the organism.

THE NATURE OF INDUCERS

The inducer of a catabolic enzyme pathway need not be the initial substrate of the pathway. It may be an intermediate or an end product of a pathway, or even a compound formed by a side reaction of an enzyme in the pathway, as for the lactose operon of *E. coli*, where allolactose is the inducer. If the inducer is produced by the action of the enzyme it induces, some small basal or endogenous level of the enzyme must always be present for the inducer to be quickly synthesized once the pathway substrate becomes available. For the lactose operon of *E. coli*, in addition to the normal promoter site for binding RNA polymerase, there is a second site that permits the synthesis of small levels of permease and β-galactosidase, even in the absence of inducer. Enough of these proteins are present in uninduced cells to permit the rapid synthesis of allolactose when lactose becomes available.

THE LACTOSE OPERON OF *STAPHYLOCOCCUS AUREUS*

Staphylococcus aureus possesses a different pathway of catabolism for lactose, using enzyme *IILac* and enzyme *IIILac* of the phosphoenolpyruvate phosphotransferase (PTS) system to transport lactose through the cell membrane. During transport, lactose is phosphorylated to phospholactose, which is cleaved by a phosphogalactosidase enzyme to form D-glucose and D-galactose-6-phosphate. The genes coding for these three enzymes are designated *lacF*, *lacE*, and *lacG*, respectively, which form an operon that appears to be under the negative control of a repressor gene (*lacR*). Interestingly, these genes are in a larger operon including *lacABCD* that encodes genes whose products are involved in the conversion of galactose-6-phosphate to tagatose-6-phosphate and the further metabolism of tagatose-6-phosphate (Rosey et al. 1991). Galactose-6-phosphate is the inducer of the *lac* operon in *S. aureus*.

THE L-ARABINOSE OPERON OF *E. COLI*

While studying the catabolism of the pentose L-arabinose by *E. coli* strain B/r, Englesberg and coworkers found differences from the regulation of the lactose operon (Sheppard and Englesberg 1967). After the transport of L-arabinose into the cells it is isomerized by the enzyme L-arabinose isomerase to the 2-ketopentose, L-ribulose. The enzyme L-ribulokinase phosphorylates L-ribulose to form L-ribulose-5-phosphate, which is epimerized to D-xylulose-5-phosphate by L-ribulose-5-phosphate. The latter compound is further degraded by other cellular enzyme systems. These three enzymes are all coordinately induced when L-arabinose is present and the genes encoding for the three enzymes are termed *araA*, *araB*, and *araD*, respectively. These genes are organized into an operon with a regulatory gene, *araC*, located next to the operon. In contrast to the *lac* operon, deletions of the *araC* gene do not lead to constitutive expression of the enzymes. Instead,

inactivation of *araC* causes the L-arabinose catabolic enzymes to become uninducible. Because the function of the regulator gene is essential for gene expression, this is termed a positive control system.

The regulatory protein, encoded by the *araC* gene, can interact with four different operator regions, O_1, O_2, I_1, and I_2, all connected to the L-arabinose operon. When *araC* binds to both the O_2 and I_1 sites, a loop is formed in the DNA preventing transcription of the operon (Huo et al. 1988). When the inducer, L-arabinose, binds to the allosteric repressor protein, the protein's DNA binding affinity changes and it now binds to operator sites I_1 and I_2, permitting transcription of the operon into mRNA.

REGULATION BY ATTENUATION

Another means of regulating the expression of biosynthetic pathways is by attenuation. The classic example of regulation by attenuation is the L-tryptophan operon in *E. coli* (Yanofsky 1981). Between the location where transcription of the operon initiates and the beginning of the first structural gene of the operon, there is a stretch of DNA termed the leader region. This region contains four stretches of sequence that, when transcribed, have the potential to form three RNA structures termed hairpins. Also located within the region are two L-tryptophan codons and an RNA polymerase pause site. As RNA polymerase proceeds through the leader region it stalls at the pause site. This delay permits a ribosome to bind to the mRNA and proceed towards the RNA polymerase. If internal L-tryptophan levels are high, then the level of tRNA charged with L-tryptophan will also be high and the ribosome can proceed to the stalled polymerase. This allows the formation of a hairpin from the downstream hairpin sites. This hairpin causes transcriptional termination. If L-tryptophan concentrations are low this causes the ribosome to stall at the L-tryptophan codons. This allows the formation of a hairpin from the middle two hairpin regions and prevents formation of the hairpin that terminates transcription. This form of regulation is different from regulation by repressor or activator proteins because transcription is allowed to proceed but the concentration of substrate determines whether the transcription will continue into the region containing the structural genes.

Reports of bacterial operons regulated by transcriptional attenuation mechanisms have been increasing (Yanofsky 2000). The *ilv* and *leu* genes in enteric bacteria are regulated mostly by a translational-dependent attenuation but the *ilv–leu* operon of *B. subtilis* is reported to be regulated, at least in part, by transcriptional attenuation (Lu et al. 1995). Regulation by attenuation has also been reported for the *E. coli* threonine and histidine operons. The *B. subtilis* aminoacyl-tRNA synthetase genes are also regulated by attenuation.

CELL-DENSITY-DEPENDENT GENE EXPRESSION

Certain genes are only expressed when the concentration of bacterial cells reaches a critical level. This cell density-dependent gene expression is termed 'quorum sensing' (Fuqua et al. 1996). The prototype quorum-sensing system is the *lux* system in the bacterium *Vibrio fischeri* (Engebrecht et al. 1983). *Vibrio fischeri* can exist as either a free-living bacterium or in the light organ of certain fishes or squid. When present in the light organs it activates the expression of the *lux* genes, which produce proteins required for bioluminescence. The expression of the *lux* genes only occurs in the light organ because cell density reaches much higher concentrations there than when the cells are present in the open ocean. Cells can sense cell density because they release a compound (the autoinducer) into the surrounding environment and the external concentration of autoinducer increases as the cell population increases. The autoinducer is freely diffusible across cell membranes, so when the concentration of autoinducer in the surrounding medium reaches the proper level, it can interact with a positive regulator in the cell that activates *lux* gene expression. Quorum-sensing systems have been found to be widespread in bacteria.

The autoinducer in *V. fischeri* and in many bacteria is a hydrophobic derivative of n-acyl homoserine lactone (Eberhard et al. 1981). In gram-positive bacteria quorum sensing takes place using a posttranslationally processed peptide (Dunny and Leonard 1997). Typically this peptide functions as a signal for the sensor component of a two-component sensor-regulator regulatory system. Examples of processes regulated by peptide-dependent quorum sensing are competence, the ability to take up DNA in *B. subtilis* and *Streptococcus pneumoniae*, the expression of virulence factors in *S. aureus*, and the production of antimicrobial peptides.

Global control networks

If more than one operon is under the control of a regulatory factor, those operons are said to constitute a regulon. Cells typically contain many overlapping regulons. Another term for a large collection of genes regulated by a common mechanism is global regulatory network. By having such global control networks, cells can quickly respond to sudden changes in the environment by increasing or decreasing the rate of synthesis of entire systems of proteins.

CATABOLITE REPRESSION

A good example of a global regulatory system is the catabolite repression system. It is not uncommon for an organism preferentially to utilize those catabolites most common in its natural environment. Therefore, bacteria given two possible carbon and energy sources simultaneously may not use them at the same time but may use

one before beginning catabolism of the other. An example is the 'glucose effect' first reported in 1942 by Gale and Epps. They found that the synthesis of certain enzymes by *E. coli* was inhibited by the presence of D-glucose in the medium. In 1947, Monod reported that the presence of glucose prevented the induction of many other sugar-catabolic pathways in *E. coli*, especially those sugars catabolized by inducible pathways. If two carbohydrates, such as glucose and lactose, were both present in the growth medium, the growth curve showed two successive growth curves separated by a lag period (Monod 1947). This was termed 'a diauxic growth curve' and it is possible to classify carbohydrates as to whether or not a diauxic growth curve results when they are incubated with glucose.

In 1961, the expression 'catabolite repression' was used to describe this type of repression of enzyme pathways. It was later shown that catabolite repression by glucose of the synthesis of β-galactosidase involves a block in the synthesis of mRNA for the enzyme. Mutants with a *lacI* deletion and, therefore, constitutive for β-galactosidase production, are still subject to catabolite repression by glucose (Magasanik 1961).

Catabolite repression in *E. coli* and other enteric bacteria

In enteric bacteria, the rate of transcription of genes that are subject to regulation by catabolite repression was found to be controlled by the intracellular concentration of a nucleotide, cAMP. The internal level of cAMP in *E. coli* is very low in cultures grown on glucose and addition of cAMP to the medium results in partially overcoming the glucose catabolite repression. Mutants deficient in adenylate cyclase, the enzyme responsible for the synthesis of cAMP from ATP, can synthesize β-galactosidase only when cAMP is added to the medium (Pastan and Adhya 1976).

Mutants were obtained that could not make β-galactosidase or similar catabolite-repressible enzymes even when cAMP was added to the medium. These mutants were found to be deficient in the synthesis of a protein named the catabolite gene activator protein (CAP) or sometimes the cAMP receptor protein (CRP). This protein was found to be a homodimer, with each monomer capable of binding one molecule of cAMP. The cAMP–CRP complex binds to DNA at the operator-distal part of the promoter region of the lactose operon and increases RNA polymerase binding efficiency. Thus, the rate of transcription of the operon is dependent upon the presence of both the CAP protein and the intracellular level of cAMP. In the presence of glucose the internal concentration of cAMP is low and the transcription of those operons requiring the cAMP–CAP complex is repressed.

The CAP protein is a global regulator of gene expression and has been found to activate transcription at more than 50 promoters. The intracellular level of cAMP appears to be regulated at least partially in growing cells by the rate of activity of adenylate cyclase. Under conditions of catabolite repression, adenylate cyclase activity is inhibited and the cellular level of cAMP decreases and, as a result, the activity of the cAMP–CAP-dependent promoters also decreases. When adenylate cyclase is active the cAMP–CAP complex forms and activates transcription through direct contact between cAMP–CAP and RNA polymerase (Busby and Ebright 1999). The cAMP–CAP complex has different affinity for different promoters so the response of separate operons may differ at any concentration of cAMP. The genes controlled by CAP are sometimes referred to as members of the carbon/energy regulon.

The activity of adenylate cyclase in *E. coli* appears to be regulated by interactions with components of the cytoplasmic membrane transport system. In the presence of carbohydrates being brought through the membrane by the PTS, adenylate cyclase is almost inactive and the level of cAMP in the cells is very low. It has been suggested that when glucose becomes limiting the phosphorylated form of enzyme IIA^{Glc} activates adenylate cyclase, resulting in the activation of adenylate cyclase and the synthesis of cAMP (Hogema et al. 1999). Phosphorylated IIA^{Glc} accumulates because no glucose is present to allow dephosphorylation. Conversely, when cells are growing upon glucose, IIA^{Glc} will transfer its phosphate group to the incoming sugar and it will mostly be present in the cell in the unphosphorylated form that does not activate adenylate cyclase.

Other mechanisms of catabolite repression

Catabolite repression also exists in bacteria such as those in the genus *Pseudomonas*. However, several studies have shown that in *P. aeruginosa* and *P. putida*, cAMP is not involved with catabolite repression. Because these bacteria receive most of their energy by oxidative phosphorylation with electrons obtained from the oxidation of acetate by the TCA cycle, it is catabolites such as acetate and TCA-cycle intermediates that cause repression of other catabolic pathways including those for glucose (MacGregor et al. 1991).

The control of catabolite repression in gram-positive bacteria may be controlled by a number of different mechanisms. No cAMP has been detected in *B. subtilis* under aerobic conditions. The addition of cAMP does not effect catabolite repression in that organism and no CAP-like protein has been identified in any gram-positive bacteria (Saier et al. 1996). *Cis*-acting sequences named catabolite responsive elements or CRE seem to be responsible for catabolite repression in *B. subtilis* and these CREs elements also have been found to function in *B. megaterium* and *Staphylococcus xylosus*. A catabolite control protein (CcpA) has been identified and mutations in this protein have been found to prevent

CRE-dependent catabolite repression in both *B. subtilis* and *B. megaterium*. CcpA has been shown either to repress or activate expression of its targets.

The exact mechanism of action of CcpA is still not understood. Repression of gene activity apparently involves the PTS system, but in a different manner than in gram-negative bacteria. During the normal function of the PTS system, the HPr protein is phosphorylated at His-15. However, in a reaction that might be unique to gram-positive bacteria, the HPr protein is phosphorylated at Seryl residue 46 by an ATP-dependent kinase, a reaction that is required for catabolite repression (Deutscher et al. 1994). HPr(Ser-P) acts as a corepressor and may directly interact with CcpA in vivo (Kraus et al. 1998).

SIGMA FACTORS

Bacterial RNA polymerases consist of at least four polypeptides termed α, β, β′, and sigma (σ). The core RNA polymerase consists of two α subunits and the β and β′ subunits, and this core unit will bind randomly to DNA. If the σ subunit is also present, the complex is termed a holoenzyme. The presence of the σ subunit directs the holoenzyme to bind at specific promoter regions and initiate transcription. After the first few nucleotides of the RNA transcript have been synthesized, the σ factor is released and the core enzyme continues the polymerization of the ribonucleotides. By the use of multiple σ factors, the cell can initiate the transcription of different regulons, thereby synthesizing new families of enzymes in response to changing environmental conditions. The RNA polymerase holoenzymes have been designated as E-σ*x*, with E representing the core polymerase and σ*x* the particular σ factor attached.

Sigma factors in *E. coli*

Lonetto et al. (1992) studied the amino-acid sequence of bacterial σ factors and classified them into three broad groups. Group I proteins are the primary σ factors. Primary σ factors from different organisms are very similar and the regions involved in promoter recognition are especially highly conserved. These primary σ factors are required for survival of bacterial cells and are responsible for most RNA synthesis in exponentially growing cells. The primary σ factor in *E. coli* is σ^{70}, which recognizes the promoters of most of the genes expressed during exponential growth. A second group of σ factors are very similar to group I but are not essential for cell growth. The third group consists of the alternative σ factors that are responsible for the transcription of specific regulons. Apparently these σ factors all compete for RNA polymerase.

Sigma factors provide another mechanism for cells to establish global regulatory networks. The ability of the cell to produce a variety of alternative σ factors with different promoter specificity allows σ factors to regulate a wide variety of physiological responses. A good example of the role of σ factors in regulating cellular responses to environmental changes is provided by the heat shock response of *E. coli*. Bacteria have evolved mechanisms that permit them to resist a variety of different environmental stresses, such as heat or cold shock, acid pH, lack of oxygen, and starvation. Bacterial response to stress is to change the expression of groups of genes known under the general term of 'stress genes.' The response of microorganisms to elevated temperatures has been termed heat-shock response. Heat-shock response is a rapid, transient increase in the rate of synthesis of certain proteins (heat-shock proteins (HSP)) within seconds of a shift of the culture to higher temperatures. If the growth temperature of *E. coli* is shifted up, for example from 37 to 46°C, the rate of synthesis of proteins concerned with transcription and translation is decreased. However, the synthesis of HSPs is increased, some by as much as 100 times. If the growth temperature is returned to normal, the rate of synthesis of these proteins returns to normal. HSPs provide the cells with some resistance to high temperatures.

Heat-shock-induced transcription in *E. coli* is associated with the heat-shock-specific σ factor, σ^{32}. The heat-shock regulon consists of over 20 genes and at least 13 promoters are known to be specifically transcribed by the holoenzyme containing σ^{32} ($E\sigma^{32}$). The actual amount of gene transcription depends upon the cellular concentration of σ^{32} and, under heat-shock conditions, σ^{32} levels increase by enhanced synthesis, elevated stability, and increased activity of the σ factor. During normal growth conditions, the σ^{32} polypeptide is very unstable in vivo, with a half-life of about 1 min. When the temperature is shifted from 30 to 42°C, the polypeptide rapidly becomes stabilized and has an eight times longer half-life (Mager and De Kruijff 1995). This change in stability is probably a result of changes in σ^{32} binding to the chaperone DnaK (Bukau 1993). When σ^{32} binds to DnaK it becomes more susceptible to protease degradation. However, when heat shock occurs, resulting in an increased association of DnaK with misfolded proteins, σ^{32} does not bind to DnaK and its turnover time of DnaK decreases. This permits it to bind to core polymerase and activate expression of target genes.

The gene encoding another sigma factor, σ^{E}, also appears to be essential for growth of *E. coli* at temperatures above 43.5°C. The activity of this σ factor appears to be directly modulated by two proteins, RseA and RseB. RseA is a membrane-bound protein that binds σ^{E}, preventing it from interacting with core polymerase. Upon heat stress RseA is probably degraded by a periplasmic protease (Ades et al. 1999). This frees up σ^{E} for interaction with core polymerase and gene activation. This regulatory mechanism suggests that genes activated by σ^{E} are involved in response to heat-shock response in the periplasm. Proteins that inactivate σ factors by directly binding them are termed antisigma factors.

The starvation of bacteria can also result in increased resistance to a variety of different stresses. This starvation effect depends to some extent upon alternative σ factors and involves the expression of starvation genes that code for special resistance factors (Nystrom 1999). This starvation-induced resistance depends upon expression of the regulons controlled by the alternative σ factors, σ^{32} and, a major regulator of the general starvation response in *E. coli*, σ^{38} (σ^{S}). Starvation causes a general response with the synthesis of 30–50 proteins. If cells of *E. coli* in the stationary growth phase are starved for glucose, they also gain an increased resistance to heat, to oxidizing agents such as hydrogen peroxide, and to sodium chloride. The 'starvation proteins' of *E. coli* are also induced by exposure to heat shock or oxidative stresses.

Sigma factors in *B. subtilis*

Another bacterium in which the role of sigma factors has been extensively investigated is *B. subtilis*. The *B. subtilis* σ factor termed σ^{A} (formally σ^{55}) is the primary σ factor present in vegetatively growing cells (Haldenwang 1995). The alternative sigma factor σ^{B} (σ^{37}) controls general stress response but is also active in cells in the stationary phase. Under nonstress conditions σ^{B} is expressed but inactivated by complexing with an antisigma factor. Interestingly, under stress conditions the antisigma factor is inactivated by a separate protein, which acts as an anti-antisigma factor (Vijay et al. 2000). A phosphorelay is involved in activating and inactivating the various factors during σ^{B} activation. Another well-studied σ factor is σ^{D}, which controls the chemotaxis-motility regulon.

Under conditions of starvation, *B. subtilis*, begins the differentiation process that results in the formation of an endospore. After the initiation of sporulation, there is an asymmetrical cell division forming two cells of different sizes. Sigma factors play an essential role in the developmental processes leading to sporulation (Haldenwang 1995). Available evidence indicates there is a cascade of interactions among the various σ factors required for sporulation. During activation of sporulation σ^{F} is the first prespore-specific σ factor, while in the mother cell, a different σ factor, σ^{E}, is the first σ factor activated. It has been suggested that σ^{F} is activated first; it somehow activates σ^{E}, and then sigma factors σ^{F}, σ^{G}, and σ^{K} are activated. The σ^{G} and σ^{K} proteins are required for activation of genes expressed late in the sporulation process.

Two-component signal-transduction systems

External environmental changes are often detected by bacteria using a system referred to as a two-component sensor regulator. This name refers to the fact that in many bacteria this sensing system is made up of a sensor kinase and a response regulator. The protein that detects the external signal is usually a transmembrane protein kinase, which transmits a signal by means of its cytoplasmic domain. Signal transfer involves transfer of a phosphate group from a histidine on the sensor kinase to the response regulator. Binding the phosphate alters the regulator's activity allowing it to bind to its target genes. A phosphatase may later remove the phosphate, restoring the system to its original state. There are many examples of two-component sensor regulator components in bacteria, although not all contain only two components. Some examples have been mentioned previously, including the nitrate-sensing system in *E. coli* and proteins sensing attractants or repellants during chemotaxis.

Altering the catalytic activity of existing enzymes

FEEDBACK INHIBITION

The regulatory processes described previously affect the expression of genes encoding proteins carrying out a particular physiological response. The process named feedback inhibition acts to decrease the activity of previously synthesized enzymatic pathways. Feedback inhibition occurs most commonly where the end product of a pathway inhibits the activity of the first enzyme in the pathway that is specific for the synthesis of that particular end product. The regulated enzyme is usually allosteric, with separate binding sites for substrate and effector molecules. In most cases the product of the pathway acts as a negative effector and, when bound to the enzyme, decreases the affinity of the enzyme for its substrate. To limit substrate flow through a pathway, it is only necessary to inhibit the activity of the first enzyme in the pathway. With the inhibition of that enzyme, the latter enzymes in the pathway will have no substrates and production of the end product must cease.

Feedback inhibition in branching biosynthetic pathways

In many biosynthetic pathways a single reaction can produce a product of which further metabolism leads to the synthesis of two or more different end products. Bacteria have developed different strategies to modulate the activity of these key reactions using feedback inhibition. One mechanism is termed cumulative inhibition. This is where the initial enzyme in the pathway has allosteric sites for each of the products eventually produced by metabolism of the product of the regulated enzyme. However, the enzyme can only be completely inhibited by the presence of multiple effectors. Because multiple pathways are dependent on the activity of the regulated enzyme, no single product should inactivate the enzyme. A variation on this regulation is concerted inhibition, which is when a single end product will not

affect enzyme activity, but when multiple products are present the enzyme is inhibited.

Another type of inhibition is termed sequential inhibition. This occurs when two or more pathways use the same substrate produced by a shared enzyme, and the pathways are subjected to feedback inhibition, resulting in accumulation of the common substrate. If that substrate then causes feedback inhibition of the enzyme producing it, feedback inhibition of the terminal pathways will result in feedback inhibition of the initial common enzyme. An alternative, but very common, method for a bacterium to regulate the activity of an enzymatic reaction shared by several pathways, is for the organism to possess different enzymes to catalyze the same reaction. Different genes encode these isozymes (or isofunctional enzymes) and, therefore, can be both repressed and inhibited separately. Regulation by means of isozymes permits each structural gene coding for an isozyme to be part of a different regulon controlled by a separate end product. The possible disadvantage of the organism having to possess genes to code for two different enzymes catalyzing similar reactions may be offset by the efficiency of regulation.

Enzyme inhibition and activation in catabolic pathways

The regulation of the activity of allosteric enzymes by effectors also functions in catabolic pathways. The effectors may be negative, inhibiting enzyme activity, or positive, activating enzyme activity. An example is the regulation of the activity of lactate dehydrogenase in homolactic acid bacteria (see above). In these bacteria, the reduction of pyruvate to lactate by lactic dehydrogenase permits the rapid oxidation of NADH that has been reduced by the hexosediphosphate pathway. If the rate of NADH oxidation is insufficient to maintain a pool of NAD^+, there will be an increase in the internal pool of fructose-1,6-bisphosphate. Lactate dehydrogenase from these organisms is an allosteric enzyme that has an absolute requirement for fructose-1,6-bisphosphate as a positive effector. The increase in the internal pool of this diphosphate results in the activation of more lactate dehydrogenase enzymes and an increase in the rate of NADH oxidation.

COVALENT MODIFICATION

Another strategy used by cells to modulate the activity of active enzymes is covalent modification. Two examples of this were discussed previously. Enzymes in *E. coli* add a phosphate to the active site of isocitrate dehydrogenase to limit its activity during growth on acetate or other compounds metabolized through acetyl-CoA (Hurley et al. 1990). The other example discussed above was covalent modification in ADP-ribosylation of nitrogenase (Ludden 1994). Modification reduces activity of the nitrogenase.

One of the best-studied examples of covalent modification is the adenylylation of glutamine synthetase in enteric bacteria. Glutamine synthetase is a critical enzyme for the incorporation of ammonia into cellular constituents. This enzyme is used for nitrogen incorporation when nitrogen concentrations are low and uses the energy of ATP to drive the reaction. Because this ATP consumption can put a significant stress on energy levels in the cell, some bacteria, such as *E. coli* and *Salmonella typhimurium*, use covalent modification to fine-tune the activity of glutamine synthetase (Merrick and Edwards 1995). Glutamine synthetase is modified by addition of AMP to the enzyme; because the active enzyme is a dodecamer, as many as 12 AMPs can be added to the active complex (Yamashita et al. 1989). Addition of the AMP reduces enzyme activity, but the active site is not directly modified. A single enzyme, adenylyl transferase/adenylyl-removing enzyme, is responsible for modification of glutamine synthetase. The activity of this enzyme is controlled by another enzyme, designated PII, which is itself covalently modified by addition of UMP. The level of uridylylation of PII is dependent on the level of nitrogen in the cell. The net result is that when fixed nitrogen is high, the activity of glutamine synthetase is reduced to minimize ATP consumption. However, when nitrogen availability is low, glutamine synthetase is deadenylylated so it can be used for the incorporation of nitrogen.

INTRODUCTION

Comparison of the current bacterial genetic literature with that of a generation ago reveal a 'sea change' in technical approach. Where once the study of bacterial genetics largely involved isolating mutants that occurred by chance in cell populations, a procedure that often required considerable ingenuity in the design of mutant selections or screens, and investigating the bases of mutation by reversion and complementation analyses, current procedure brings to bear a panoply of powerful molecular genetic techniques that enable an investigator to determine precisely a gene's composition and its mode of expression. These techniques include genomic and proteomic analyses supported by the computational power of bio-informatic databases. This chapter will discuss some of these technologies, and will attempt to indicate the value of both old and new approaches.

The similarities displayed among bacteria and the differences that distinguish one from another reflect the content and expression of the genes possessed by each individual cell. The genes control every property of a cell, including morphology, physiology, biochemistry, and, in general, an exact copy of each one is inherited by the cell's progeny. Genetics is the study of genes, their structures, organizations, and expression.

With the exception of some bacteriophages (see Chapter 5, Bacteriocins and bacteriophages), the genetic information of bacterial systems is encoded in DNA. The characteristics expressed by a cell are referred to as its phenotype. The set of genes found in any particular cell constitutes its genome, which generally consists of a large circular DNA molecule, the bacterial chromosome, and possibly one or more smaller circular DNA molecules called plasmids (Charlebois 1999).

Bacteria are, in general, very adaptable and may alter their phenotype in response to environmental change while the genotype remains unchanged. The ability to adapt the phenotype to the prevailing environmental conditions is determined genetically, i.e. not all the genes of a bacterial cell are expressed all the time. For example, β-galactosidase, an enzyme that hydrolyzes lactose to its constituent sugars, glucose, and galactose, is required by *Escherichia coli* only when lactose is its main source of carbon and energy and normally it is produced only under such circumstances (Jacob and Monod 1961; Prescott et al. 2002). The gene (*lacI*) and associated sequences that control the expression of β-galactosidase are, together with the gene for β-galactosidase itself, *lacZ*, and two other associated genes, *lacY* and *lacA* encoded at essentially the same location on the *E. coli* chromosome. The three genes *lacZ*, *lacY*, and *lacA* together form the *lac* operon, a set of genes that is expressed from a single promoter to produce, in the first instance, a single transcript (polycistronic mRNA) (Chapter 3, Bacterial growth and metabolism). This, in turn, is translated to produce the three gene products of the *lac* operon. This is just one example of the many complex systems that can be switched on or off to allow bacteria to make best use of the nutrients available to them and to adjust their biochemical makeup rapidly in response to changes in their environments. Such switches in gene expression generate phenotypic variation; the phenotype of the cell changes while the genotype

remains unaltered. By contrast, genotypic variation involves a change in the genetic information that determines the phenotype. This type of change can occur by mutation, i.e. an alteration of the nucleotide sequence of DNA, that can occur in one of several ways. Alternatively, gene content can be changed by acquisition of new genes from another bacterial cell, by one of three DNA transfer processes, transformation, transduction, or conjugation.

In general, all the cells in a bacterial culture respond phenotypically in the same way to a change (often nutritional) in their environment. The change in phenotype is normally rapid and reversible, e.g. synthesis of the enzyme β-galactosidase by *E. coli* starts within seconds of the addition of lactose to a suitable culture medium and ceases just as rapidly when lactose is withdrawn (or exhausted). In contrast, genotypic change (mutation) affects the individual cell, rather than the population, and is essentially permanent. There are, however, exceptions to these generalizations and it is sometimes difficult to determine into which category a particular variation fits. For example, lysozyme treatment of a culture of *Bacillus subtilis* converts the cells to protoplasts by removing the cell wall. Removal of lysozyme, however, does not always result in a return to normal cell physiology; the cells may continue to grow as protoplasts or may show mass reversion to the bacillary form, depending upon the conditions of culture. This is an example of a phenotypic change that, in some circumstances, can appear as heritable and permanent. By contrast, physiological changes resulting from mutation may give the impression of being phenotypic because bacteria can multiply so rapidly; a mutant cell, with a particular selective advantage, can overgrow a population of unaltered cells within a few hours. When the culture conditions are reversed, the mutant may be at a selective disadvantage and, in turn, may be overgrown by cells of the original type. If cells are examined on time scales that permit many generations, what is in reality genotypic variation may appear to be phenotypic variation.

Bacteria are haploid organisms with no true nucleus or sexual reproductive cycle. The first great expansion of knowledge of bacterial genetics followed the discovery that genes (DNA) can be passed from one bacterial cell to another by several mechanisms. The second major expansion of activity is now in progress and reflects the introduction of a raft of molecular genetic techniques such as restriction enzyme mapping, gene cloning, DNA sequencing, and site-directed mutation. The bacterium about which most is known is *E. coli* K12, whose single chromosome is a circular DNA molecule of approximately 2 mm, about 1 000 times longer than the bacterial cell in which it is contained. This DNA molecule contains c. 4 700 000 base pairs (bp) or 4 700 kilobases (kb), and accommodates approximately 4 300 genes. Other bacteria also have single circular chromosomes; this is true both of bacteria related to *E. coli*, such as *Shigella* and *Salmonella* spp. (Sanderson 1976), and of unrelated ones such as *Pseudomonas aeruginosa* (Holloway et al. 1979) and *B. subtilis* (Henner and Hoch 1980). Chromosome size varies considerably from one species to another. The smallest recorded to date is that of the intracellular pathogen *Mycoplasma genitalium* at 600 kb, while the largest found so far is the 9 455 kb circular chromosome of *Myxococcus xanthus*, closely followed by that of *Stigmatella aurantiaca* (9 350 kb) (Cole and Saint-Girons 1999). However, circular chromosomes are not a universal feature of prokaryotes. Linear chromosomes have been discovered in several bacteria, including *Borrelia burgdorferi*, the Lyme disease agent (which has a single linear chromosome of approximately 950 kb), *Agrobacterium tumefaciens*, which induces the formation of galls on a number of plants and has one circular chromosome (3 000 kb) and one linear one (2 100 kb), and *Streptomyces* species, sources of many antibiotics, which have linear chromosomes of approximately 8 000 kb (Cole and Saint-Girons 1999; Leblond and Decaris 1999). Circularity of the *E. coli* chromosome was first established by gene linkage experiments, and this provided the paradigm for several other bacteria. In the case of *E. coli* K12, its chromosome was also extracted and visualized (by autoradiography) and shown unequivocally to be circular (Cairns 1963), so confirming the genetic data. In more recent times, the form of a bacterial chromosome has more commonly been established by physical techniques such as restriction mapping. Restriction endonucleases are used to fragment the DNA molecule and the fragments are separated and their sizes determined by pulsed-field gel electrophoresis (PFGE). Fragment contiguity (fragment order) is determined in a number of ways, including cross-hybridization, which involves isolating and labeling a genomic fragment and using it as a probe to identify neighboring sequences. A summary of the different approaches to genome analysis and results obtained have been reviewed by Cole and Saint-Girons (1999). Now, chromosome circularity is much more readily established by complete genome sequencing programs. In addition, many bacteria carry relatively small DNA molecules called plasmids. These may also be circular or linear. Many are itinerant molecules that can be passed from one bacterial cell to another. Examples par excellence of this type are the resistance (R) plasmids responsible for much of the acquired antibiotic resistance displayed by many human bacterial pathogens. However, carriage of some plasmids appears to be a universal feature of a particular bacterial species (Cole and Saint-Girons 1999), in which case they appear to be indispensable and can be thought of as mini-chromosomes. The results of all of these studies have established that circularity is the norm for bacterial DNA, but there are exceptions, as noted.

Bacterial chromosomes must replicate before cell division and be distributed (partitioned) so that each daughter cell has its own copy. A complex organization

exists to ensure that this happens. Plasmids also encode replication functions that allow them to replicate independently of the bacterial chromosome of the host cell and many also encode partition functions, as well as other stabilization mechanisms. DNA molecules that replicate are called replicons (Jacob et al. 1963). The chromosome is the replicon(s) in which are encoded those genes that are essential for the cell's survival. It is also the largest replicon in the cell. However, as indicated in the previous paragraph, not all bacteria carry their essential genes on a single DNA molecule. In a few instances, such as *Brucella melitensis*, *Burkholderia cepacia*, and *Rhodobacter sphaeroides*, the genome comprises two or more large DNA molecules, which are essential to the cell (Cole and Saint-Girons 1999).

MUTATION

Mutation can be defined as any permanent change in the sequence of bases of DNA, irrespective of a detectable change in the cell phenotype. In practice, most mutations are detected by virtue of the change in phenotype generated, although now, with many DNA sequences being determined, it is found that silent mutation is very common, i.e. a change in the nucleotide sequence that has no detectable phenotypic effect. Indeed, silent mutation is a major feature of genetic drift within a bacterial species, and can be used for typing purposes (van Leeuwen et al. 2003). A given gene can exist in a variety of different forms – some functional, some not – as a result of mutation. These different forms are called alleles. The form in which a gene exists in a bacterium as it is first isolated from nature is defined as the wild-type allele of the gene; all other forms resulting from mutation of that gene are, by definition, mutant alleles.

Mutations may occur spontaneously, i.e. in the absence of a specific treatment to generate them, or they may be induced deliberately (the cells of the bacterial culture may be treated in one of several ways so as to provoke changes in the base sequence of the DNA). Classically, induction of mutations has been achieved by chemical treatment with known mutagens such as ethylmethane sulfonate (EMS, $CH_3CH_2.O.SO_2.CH_3$) and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG, NTG) or by irradiation with ultraviolet or X-rays. These treatments generate DNA lesions at random and the particular mutation desired is selected by judicious manipulation of the subsequent growth conditions of the culture. In recent years it has become possible to target mutations, i.e. to introduce specific changes into a particular nucleotide sequence, using recombinant DNA technology, a procedure termed site-specific mutagenesis.

The spontaneous nature of mutation was demonstrated by Luria and Delbruck (1943) by an experiment known as the fluctuation test. The experiment exploited the observation that in a large enough population of cells sensitive to a particular bacteriophage (phage) there will be a few cells resistant to the phage. When equal volumes of a broth culture, each containing approximately 10^9 *E. coli*, were spread on a nutrient agar seeded with the phage, the number of colonies arising from resistant cells showed a small fluctuation from plate to plate (Figure 1). In a parallel experiment, small inocula (c. 10^3 cells) of the same culture were used to produce a series of 50 separate broth cultures. When the same volumes of these (i.e. containing approximately 10^9 bacteria) were spread on agar seeded

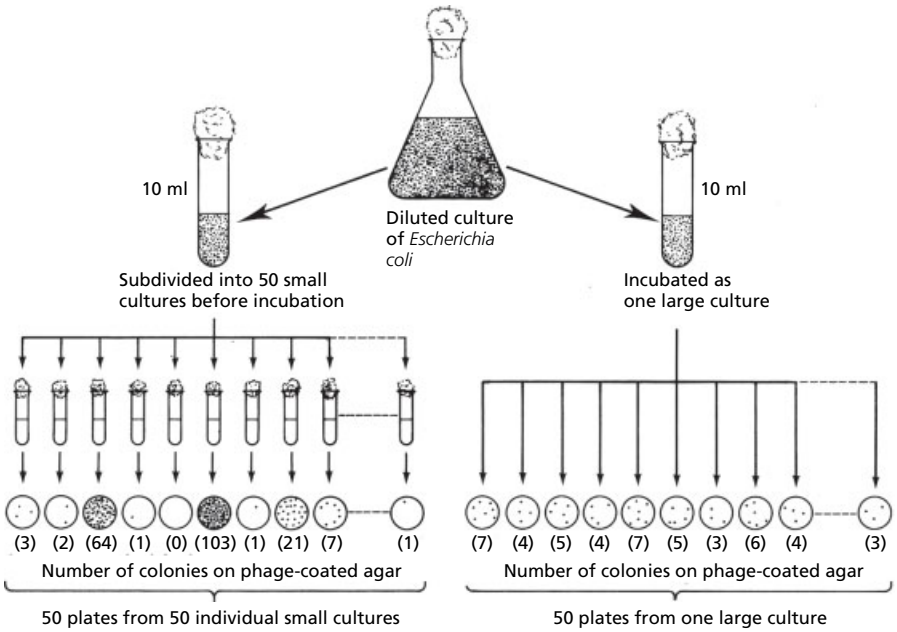

Figure 1 *Proof of the non-directed (spontaneous) nature of bacterial mutation by the 'fluctuation test'*

with the phage, much larger fluctuations were seen in the number of colonies obtained per plate (Figure 1). The results reflected the random nature of the mutations that had occurred in each culture, i.e. mutations arose at different times during the growth of the different cultures (the earlier the mutant appears the greater is the proportion of resistant cells in that population).

That mutations can arise spontaneously in a population of cells, independently of selective forces, was demonstrated directly and elegantly by Ester and Joshua Lederberg (1952). Approximately 10^8 phage-sensitive *E. coli* cells were inoculated onto nutrient agar and the plate was incubated. The resulting colonial growth was replica-plated to nutrient agar and nutrient agar seeded with the phage, where only phage-resistant cells grew to form colonies. Each colony that developed came from an inoculum of a phage-resistant cell (or cells) on the master plate. The locations of these were determined, and approximately 10^5 cells from the identical position on the phage-free nutrient agar were transferred into tubes of broth. From each of the resulting cultures 10^5 cells were spread on individual nutrient agar plates. The colonies that developed were again replica-plated to nutrient agar and nutrient agar seeded with phage and the entire process was repeated several times. By picking only phage-resistant colonies (identified by growth on the replica plate containing nutrient agar seeded with phage) from the phage-free nutrient agar to generate cultures for further testing, it was possible, eventually, to obtain a pure culture of a phage-resistant mutant. During the entire procedure the populations of cells used in the purification steps were never exposed to the phage, demonstrating unequivocally that resistant variants (i.e. mutants) emerged in the complete absence of the selective agent.

Mutagenesis

Much of our understanding of the mechanisms of mutation derives from experiments in which mutations have been induced by chemical agents that react with DNA in a known manner. Experiments designed to study the chemical basis of mutation have been carried out extensively with *E. coli* and several bacteriophages for which *E. coli* is a normal host. The protocols of mutation experiments vary according to the particular mutagen to be tested. For those reagents that react chemically with the constituent bases of DNA, bacteria are mixed with the mutagen and the suspension is incubated. The concentration of mutagen used and the time of incubation are determined pragmatically as those conditions under which approximately 5 percent of the input cells survive the treatment. The survivors are then permitted to grow in normal culture. Among the population that results, the proportion of mutants is high; in practice, however, the abundance of a particular mutation, although considerably enhanced with respect to the untreated starting culture, may still be below the level at which a screen of individual cells in the population would readily detect it. Hence, populations of cells obtained after mutagenic treatment may be subject to culture on selective growth medium, constituted to favor the growth of the desired mutant.

Some chemicals cause mutation because they mimic one of the constituent bases of DNA and may be incorporated into DNA during replication when present in the growth medium. 5-Bromouracil (5-BU), an analog of thymine with a bromine atom at the C-5 position instead of a methyl (CH_3) group, is one such compound. Once part of DNA, such substitutions cause misincorporation of normal bases in subsequent rounds of replication, e.g. 5-BU causes misincorporation of guanine. For these mutagens the cells must necessarily grow during treatment because DNA replication is essential for the effect. The concentration of the reagent has to be chosen so that the level of incorporation is high enough to raise the frequency of mutation but not so high as to kill the majority of cells in the treated population. Again, the conditions of treatment are determined pragmatically.

One easy way to decide if the mutagenic treatment has been successful is to examine the culture for an increase in the proportion of a particular class of mutants, for example auxotrophic mutants or antibiotic resistant mutants. Experimentally, the percentage of auxotrophs generated, i.e. mutants that have acquired a nutritional requirement, or the percentage of antibiotic resistant derivatives generated, is determined. For example, samples of a suitable dilution of a mutagenized culture of *E. coli* are spread onto nutrient agar, so as to give 100–150 colonies per plate after a suitable period of incubation. These colonies are then tested individually, by replica plating, to determine if they can grow on a minimal-salts agar that supports growth of the parent bacterium. A satisfactory mutagenic treatment will generate 5–10 percent auxotrophs that will be unable to grow on the minimal agar. Alternatively, the increase in the proportion of cells resistant to certain antibiotics, e.g. rifampicin, streptomycin, or nalidixic acid, to which the cells in the treated culture were susceptible before treatment, can be monitored.

Various experimental 'tricks' can be used to enhance the chances of success in finding a particular mutant. Two are worthy of mention. The abundance of particular auxotrophic mutations in a population can be increased by penicillin enrichment to the point where they form the majority. Penicillin kills only growing bacterial cells. Non-growing cells survive the treatment, provided the medium is osmotically buffered. Hence, a whole mutagen-treated culture is inoculated into liquid medium lacking the particular growth factor (e.g. amino acid, vitamin, purine, or pyrimidine) needed by the desired auxotroph. After a short incubation (15–20 min), during which time the growth of the mutant type

required is arrested, penicillin is added to the culture. The cells that do not need an exogenous supply of the growth factor grow and most are killed by the penicillin. The auxotrophs, because their growth has been arrested, survive. On removal of the penicillin and inoculation into a growth medium supplemented with the growth requirement, these cell types proliferate, together with any other survivors, to generate a new population of cells, among which the desired auxotrophs constitute an increased proportion. In practice, the procedure is not an all-or-none effect and a single round of treatment rarely increases the proportion of mutants sought by more than 100-fold. However, four or five cycles of treatment can usually enhance the proportion of the auxotroph required to greater than 10 percent of the surviving population of cells (Miller 1972), at which point mutants are easily identified. The procedure can be adapted to recover any mutant type where the mutation creates a conditional inhibition of growth that can be experimentally exploited.

The second technique that has been indispensable in the search for bacterial mutants is replica-plating (Lederberg and Lederberg 1952). Velvet is pressed gently onto the surface of agar on which bacterial colonies of interest have grown. A sample of each colony is imprinted on the velvet, which is then used to inoculate plates of sterile agar differing in composition from that on which the colonies originally appeared. The procedure preserves the pattern of colonies on the original plate. After incubation, the ability of individual colonies to grow under the new conditions can be assessed; e.g. a population of cells can be screened for auxotrophs of a particular type by replica-plating from a medium supplemented with the growth factor in question to a medium that lacks the growth factor but which is otherwise the same. The desired auxotrophs will fail to grow. An experienced person can easily screen 200–300 colonies per plate and, if necessary, several hundred plates per day.

Mutations can be divided into two types, micro- and macrolesions, depending on the extent of the alteration to the base pair sequence of DNA. Microlesions are also known as point mutations.

Microlesions

Point mutations are of two classes: base pair substitutions and frame-shift mutations. The first class comprises those mutants in which a single base pair has been altered, and can be subdivided into transitions and transversions. Such changes may be expressed (i.e. are detected as an altered phenotype) or silent. Frame-shift mutations are those in which one or a few base pairs have been added to or removed from the DNA with the consequence that the translational reading frame of the transcript, i.e. of messenger RNA (mRNA), of the mutated gene is altered. Point mutations are, in general, revertible, i.e. a second mutational event at the same site can precisely reverse the first mutation and restore the original base sequence.

A transition occurs when one purine is replaced by another purine and a pyrimidine is replaced by a different pyrimidine, e.g. a change from a guanine–cytosine (GC) base pair to an adenine–thymine (AT) base pair, or vice versa; in this situation the purine–pyrimidine axis of the double helix at the point of mutation is preserved. Most chemically induced base substitutions are transitions. Transversions are those base pair substitutions in which the purine–pyrimidine axis is changed as a result of the mutation, e.g. a change from GC to CG or to TA. Such changes are much less common than transitions and probably arise as a consequence of occasional mistakes made during DNA replication and by one or more of the cell's DNA repair systems.

All four of the bases in DNA can exist in different tautomeric forms which are related to each other by single proton shifts. The tautomeric forms arise when the keto (C=O) group of a base is changed to the enol (C–OH) form or when the amino ($-NH_2$) group is changed to an imino (=NH) group. The enol and imino groups exist in equilibrium with the keto and amino forms, respectively, but the latter predominate under normal conditions, i.e. at ambient temperatures and at pH values near neutrality. Such tautomeric shifts are important because they can relax the normally strict Watson and Crick complementary base pairing conventions, permitting, for example, G to pair with T instead of with C, while retaining purine–pyrimidine base pairing. Such mistakes do occur during replication but they are kept to a minimum by the intrinsic accuracy of most DNA polymerases together with associated proofreading functions (Kunkel and Bebenek 2000) and by DNA mismatch repair systems (Harfe and Jinks-Robertson 2000; Marti et al. 2002). If these occasional mispairings are not corrected, on replication one daughter chromosome will have, for example, an AT base pair at a particular location instead of a GC base pair, and mutation will have occurred. These different forms are illustrated in Figure 2.

As well as occurring naturally, transitions may be formed by the incorporation of base analogs into the DNA. Among the most important analogs are the halogenated pyrimidines, particularly 5-BU. This compound can be incorporated into DNA in place of thymine. The halogen atom is strongly electronegative and can pull electrons from the oxygen of the keto group of 5-BU, converting it to an enol group. 5-BU and similar analogs, therefore, tautomerize much more readily than the natural base under normal physiological conditions. In its keto form, 5-BU can pair with A and be incorporated into DNA to form a pseudo-AT base pair. If 5-BU then undergoes a tautomeric shift to the enol form, at the next round of replication it will direct the incorpora-

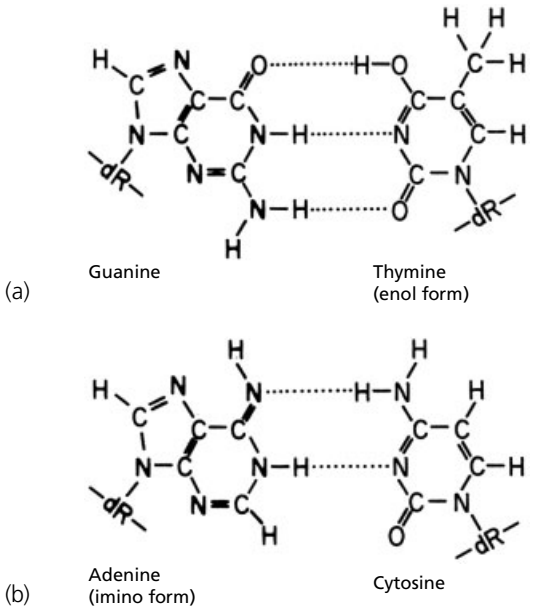

Figure 2 *Changes in base pairing as the result of tautomeric shifts. In the enol form* **(a)**, *thymine forms hydrogen bonds with guanine, instead of with adenine. In the imino form* **(b)**, *adenine forms hydrogen bonds with cytosine, instead of with thymine. Similar shifts in guanine and cytosine will also cause changes in base pairing.*

tion of G rather than A into the newly synthesized strand of DNA. A further round of replication will establish an AT to GC transition. Because they are incorporated into DNA by replication, base analogs are effective as mutagens only in growing cells. By contrast, other chemicals such as nitrous acid and various alkylating agents interact with non-replicating and replicating DNA.

Transitions can be generated by the action of nitrous acid. This chemical reacts with amine groups, converting them to hydroxyl groups (oxidative deamination). Deamination of adenine converts it to hypoxanthine, which can base pair with cytosine. Therefore, upon replication, hypoxanthine may cause misincorporation of C. A further round of replication will then establish the AT to GC transition. In similar reactions, thymine is converted to uracil and guanine is converted to xanthine. The first of these changes can be detected by a dedicated repair system and reversed (Pearl 2000), whereas the latter appears to be lethal rather than mutagenic.

Alkylating agents are powerful mutagens that predominantly generate transition mutations, although some have been reported to generate transversions and frameshifts as well; the mechanisms by which the latter changes are achieved are not fully understood. Alkylating agents all carry one, two, or more reactive alkyl groups. An example, widely used to generate bacterial mutants, is EMS. The action of alkylating agents on DNA is complex. They are known to react with purine bases, predominantly guanine, and the alkylated bases can cause base misincorporation if the damage is not corrected before replication. Bifunctional alkylating agents, i.e. those with two or more reactive alkyl groups, bring about cross-linking of the two strands of the double helix. This reaction is not, of itself, mutagenic but is lethal because cross-linking the strands of the double helix inhibits replication. However, attempts by the cell to repair the damage may result in mutation.

Transversions may arise spontaneously or may be induced at low frequency by some mutagenic treatments. However, no known chemical or irradiation treatment generates transversion exclusively, or even predominantly. Less is known about the mechanisms that generate transversions than about those that generate transitions, but many are probably due to replication or repair errors, rather than to the direct consequence of mutagenic treatment.

Acridine dyes induce frameshift mutations. The properties of these mutations are accounted for by the insertion (+) or deletion (−) of one, or a few, base pair(s) in DNA. Because the information encoded in mRNA is read as a sequence of triplets, insertion, or deletion of bases (other than multiples of three) causes a shift in the reading frame with the result that all codons (triplets) beyond the site of mutation are changed; a second frameshift, of similar magnitude but opposite sign, will correct the reading frame beyond the second mutation. If the amino acid sequence encoded by the base sequence between the two sites of mutation is not critical to the function of the gene product, the two mutations may cancel each other out and an altered but functional peptide may be produced. This is an example of pseudoreversion; the lost phenotype is restored by the second mutation but the original mutation remains. When this occurs, the second mutation is said to be a suppressor of the first and, because it is within the same gene, the phenomenon is termed intragenic suppression. When separated from the primary mutation by recombination, an intragenic frameshift suppressor mutation acts exactly like a primary frameshift mutation. Some frameshift mutations, particularly those that result from nucleotide insertions, will also revert precisely. Although frameshift mutants revert to the wild-type phenotype spontaneously and can be induced to revert at a higher rate by acridine dyes, frameshift mutations are never induced to revert by base analogs, nitrous acid, or hydroxylamine.

One of the best known acridine dyes is proflavine. Because it is a planar (flat) molecule with dimensions similar to that of a purine–pyrimidine base pair, it can intercalate between the stacked bases of DNA. It has been proposed that proflavine exerts its mutagenic effect on DNA undergoing recombination. This idea arose from the observation that while proflavine is a relatively poor mutagen for normal cells of *E. coli*, its mutagenic effect is considerably increased, (1) in the case of *E. coli*

bacteriophage T4 which indulges in a considerable degree of recombination during the course of its development; and (2) with partial diploids of *E. coli* formed during bacterial conjugation as the result of incomplete transfer of the chromosome of one bacterium to another. In the latter system, frameshifts are generated at a higher frequency in that region of the genome that is temporarily duplicated than in the remainder. Recombination of DNA involves breakage and reformation of phosphodiester bonds and it has been proposed that frameshift mutagens act by temporarily stabilizing mispaired sequences that may form following strand cleavage and transient strand separation. All frameshift mutagens are intercalating agents, but not all intercalating agents are frameshift mutagens. Another common intercalating agent, widely used in molecular genetics, which is a frameshift mutagen is ethidium bromide.

In practice, when studying a mutagen or suspected mutagen, it is easier to gauge its effects on the frequency of reversion of a set of known point mutants than to analyze its ability to generate 'knock out' mutations in a particular gene(s). Although reversion frequencies are generally somewhat lower, analyzing reversion offers considerably more sensitivity and convenience. This is the basis of the well-known Ames test, used to test chemicals to determine if they are mutagenic (and so, potentially carcinogenic) (Ames et al. 1973; Ames 1979).

Transition, transversion, and frameshift mutations generate alterations in the sense of the mRNA transcript. A mis-sense mutation gives rise to a codon that specifies an amino acid different from that originally encoded. The effect on the polypeptide product depends on the position of the altered amino acid and the precise nature of the change. In some cases, the polypeptide may show no obvious change in its properties; in others, all protein function may be lost. The change may generate a protein with altered thermal stability such that at a relatively low (permissive) temperature the protein functions more or less normally, whereas at higher (nonpermissive) temperatures the protein is nonfunctional; if this results in cell death the mutation is said to be a conditional-lethal mutation, i.e. the mutation is lethal, but only at the elevated temperature. In the case of most enteric bacteria, such as *E. coli*, the permissive temperature would normally be 30°C and the nonpermissive 42°C. There are many other examples of conditional-lethal mutants in which a potentially lethal mutation can be tolerated under particular physiological conditions. Such mutations can be invaluable when studying a vital component of the cell.

Point mutations may change a codon from one specifying an amino acid to one specifying termination of protein synthesis, namely UAG, UAA, or UGA, when a truncated polypeptide is produced instead of the full-length protein. Such mutant codons, when they appear within a gene, are called nonsense codons because they do not code for an amino acid. The introduction of a nonsense codon into an early gene of an operon may produce an effect known as polarity (Zipser et al. 1970). An operon consists of a set of genes that are transcribed as a single mRNA. A polar mutation is one that results not only in the loss of expression of the mutated gene but also in loss or significantly lower expression of those genes in the operon located distal to (or downstream from) the nonsense mutation, i.e. located on the opposite side of the mutation to that of the operon promoter. Translation of mRNA ceases at a nonsense mutation, the nascent peptide is released and ribosomes are discharged. Some may reattach to the mRNA downstream of the mutation at an appropriate ribosome binding site preceding the next translation start signal. When fewer than normal reattach, polarity results. In some instances the polar effect is so strong that genes distal to the nonsense mutation are barely expressed, if at all. Transcription of most genes is coupled to translation of the transcript. If these processes are uncoupled, transcription may also be terminated prematurely as a consequence of what is termed rho-dependent transcription termination (Landick et al. 1996). Severe polar effects are often related to the location of the mutation close to the start of the mutated gene, when translation is uncoupled from transcription for a prolonged distance. In such instances, mRNA distal to the point mutation is either not synthesized, due to premature transcription termination (attenuation), or is synthesized in considerably reduced quantities (Adhya and Gottesman 1978). This coupling of mRNA synthesis to its translation has evolved in some systems to provide a sensitive mechanism of control of enzyme synthesis termed attenuation (for further details, see Yanofsky 1987; Landick et al. 1996).

Suppression of base substitution mutations

As in the example of frameshift mutations, it is sometimes possible to have a second mutation at a site different from the first, the result of which is restoration of the lost phenotype. Such second site mutations are examples of suppressors, and the double mutants are again referred to as pseudorevertants. Mutations due to base substitutions may be suppressed by either an intragenic mutation or by an intergenic mutation, in which case the second mutation is in an entirely different gene from the first. In the former case, the suppressor mutation alters a second amino acid in the polypeptide; the second substitution neutralizes the damaging effect of the first and restores protein activity. Again, if the second mutation is separated from the first by recombination, it may also impose a mutant phenotype. Such suppressors are quite specific for the original mutation.

Intergenic suppression operates primarily at the level of protein synthesis. Mutations of this type mostly give

rise to altered transfer RNA (tRNA) molecules, although alterations in ribosome components, the so-called *ram* alleles of ribosomal protein genes, have been reported (Andersson and Kurland 1983). The altered tRNA molecules are able to read one, or sometimes two, of the three nonsense codons (UAG, UAA, and UGA) as an amino acid codon (Engelberg-Kulka and Schoulaker-Schwarz 1996). The change in specificity is, in many cases, the result of a base pair substitution in the DNA sequence that determines the anticodon of the tRNA species generating an anticodon to one of the terminating codons. Such suppressors will recognize the cognate codon, i.e. a particular nonsense mutation, wherever it occurs and will translate it. The efficiency with which a nonsense codon is translated by an appropriate suppressor tRNA will be determined by how effectively the mutant tRNA competes with the normal translation termination factors, which will also react to the nonsense codon, and the influence of the nucleotide context, i.e. the surrounding sequences within which the terminating codon appears (Bossi 1983). The affinities of both factors for the nonsense codon are known to alter with the context of the codon.

It was thought initially that suppression must be highly inefficient if the cell is to survive. This is now known not to be true and individual suppressors can translate nonsense codons with efficiencies of 60–75 percent. By contrast, some suppressors are relatively inefficient but, for many enzymes, even a small level of production, say 5 percent of the wild-type level, is sufficient to permit growth of the cell, albeit often with a lower growth rate than the original parent strain.

The generation of a suppressor, i.e. mutation of a tRNA gene, can be tolerated only if the cell produces an alternative tRNA with which it can translate the codons that the mutant tRNA would have recognized before its mutation, otherwise protein synthesis will be fatally compromised (Murgola 1985). In many cases this is possible because there is a redundancy of tRNA species for a number of codons. Hence, one of them can be mutated to recognize a different, but related, codon with little or no damage to the protein synthetic apparatus of the cell.

Since tRNA suppressors may be generated by mutation of the anticodon sequence, it should, in principle, be possible to isolate mis-sense suppressors as well. Several of these have indeed been isolated. They tend to involve minor species of tRNA and their efficiency of suppression is low but effective for the reasons given above. In addition, tRNA frameshift suppressors have also been isolated where the mutations are insertions in the anticodon sequences that increase their sizes from three to four bases (Engelberg-Kulka and Schoulaker-Schwarz 1996).

The importance of tRNA suppressors rests in the fact that they have been used extensively, particularly before gene cloning and sequencing was more or less routine, to demonstrate that mutations were located within nucleotide sequences that encode peptide products, since the effectiveness of such suppressors depends on their abilities to decode mutant codons and restore function to the protein affected by the mutation. Their existence also helped to establish the current model of protein synthesis.

Macrolesions

Alterations of DNA involving large numbers of base pairs are of four types: deletions, duplications, inversions, and additions. Deletion mutations are recognized by their inability to revert and by their failure to recombine with two or more distinct point mutations. A number of mechanisms can be proposed to explain the generation of deletions, including errors in replication, in recombination and in DNA repair. In addition, the activities of transposable elements can and do generate deletions.

Errors in DNA replication (copy errors) involve sequence duplications and slippage of one strand of the replicating DNA in relation to the other. A disruption in the pairing between the parental template strand, DNA polymerase and the newly synthesized daughter strand could lead to either of the two results outlined in Figure 3. After having separated transiently, the two strands re-anneal, but misalign because of the sequence duplication. The misalignment is accommodated by one of the strands looping out part of its sequence. A 'jump ahead' in copying produces a deletion in the daughter strand; a 'jump back' produces a sequence duplication.

Deletions and inversions may result from intra- and inter-replicon recombination, as outlined in Figure 4. These events also require sequence duplications. Recombination between homologous sequences carried in the same orientation on the same DNA molecule results in the loss of one copy of the duplicated sequence and of the sequence between the duplication. Recombination between homologous but inverted sequences inverts the intervening sequence. Inter-replicon recombination between regions that have sequence duplications may result in sequence duplication in one of the DNA molecules involved and deletion in the other (what is lost by one molecule is gained by the other) (Figure 4).

Mutations induced by ultraviolet light

Mutations may be induced by ultraviolet (UV) light. DNA strongly absorbs UV light at an absorption maximum of c. 260 nm. Cells are killed by UV light and there is a high proportion of mutants among the survivors. The most frequent lesion introduced into DNA by UV irradiation is the formation of pyrimidine dimers; covalent bonds are formed between adjacent pyrimidines on the

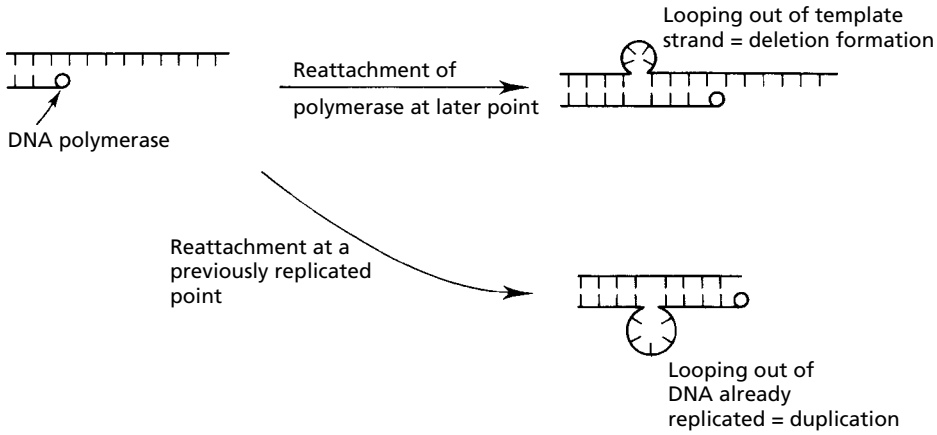

Figure 3 *Errors in DNA replication*

same DNA strand so that the two pyrimidine residues are joined by a cyclobutane ring. The most common are thymine dimers, but cytosine dimers and thymine–cytosine dimers are also generated. The appearance of these dimers distorts the shape of the DNA molecule (i.e. distorts the double helix) by interfering with normal base pairing. Because of the distortion, DNA replication stalls at thymine dimers. Replication may be reinitiated some distance away from the lesion, so generating a gap in the daughter strand. Unless repaired, the generation of a pyrimidine dimer is a lethal event. Not surprisingly, cells, from bacteria to higher eukaryotes, have evolved a number of mechanisms to repair pyrimidine dimers and restore the normal base sequence. If UV-treated bacterial cells are immediately exposed to visible light of wavelength 300–400 nm, both mutation frequency and lethality are greatly reduced, a phenomenon called photoreactivation. The visible light treatment activates an enzyme, photolyase, that hydrolyzes the cyclobutane ring, precisely reversing the reaction mediated by exposure to UV. The mechanism is accurate and error free. In addition, the cell has various repair systems that do not need light stimulation: the dark repair processes. One or more of these systems is error prone and it is the activity of this system (or systems) that can result in mutation (Altshuler 1993; Sinha and Hader 2002). DNA replication is involved and is mediated by DNA polymerases, which are intrinsically error-prone in terms of accommodating non-

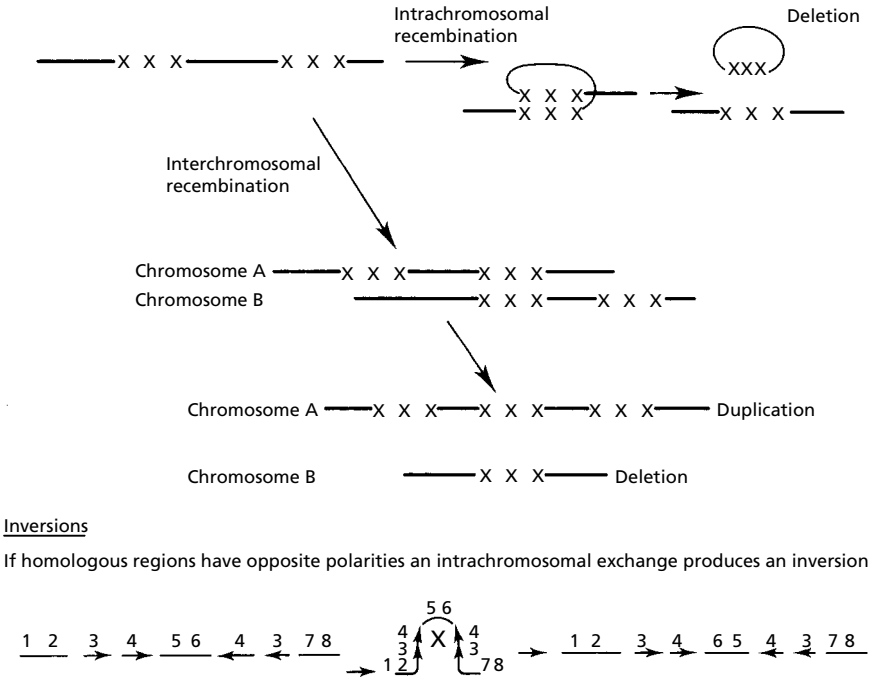

Figure 4 *Inter- and intrachromosomal recombination*

Crick–Watson base pairing during daughter-strand synthesis. This gives them the ability to replicate through damage to DNA, such as the presence of pyrimidine dimers, albeit with a high probability of introducing mistakes at that point (Goodman 2002; Woodgate 2001).

Other types of mutation

Spontaneous mutations may occur in the absence of known mutagenic treatment. There are probably many reasons for this. Various products or intermediates of the cell's own metabolism are demonstrably mutagenic; these include peroxides, nitrous acid, formaldehyde, and purine analogs. Some spontaneous mutations may, therefore, be induced by endogenously generated mutagens. Alkaline pH and elevated temperature have also been implicated in mutation.

Finally, it has been discovered that certain mutations of bacteria themselves predispose the cell to further mutation. Several loci are now known to be involved. They include functions connected with DNA replication and, particularly, with a process termed mismatch repair (Chopra et al. 2003), that operates to maintain the integrity of the genetic message (Schofield and Hsieh 2003).

In these cases the initial mutation diminishes the reliability of either those functions that ensure the fidelity of replication (i.e. the error rate is increased) or one of the DNA repair mechanisms, the purpose of which is constantly to scan the cell's DNA for damage and correct it when found. These mutations generate alleles called mutator (*mut*) genes because they enhance the frequency of mutation (Hutchinson 1996). There is a similar mutator gene in coliphage T4, whose product has been identified as a DNA polymerase. Mutator genes have been reported to induce transversions at relatively high frequencies, consistent with a partial breakdown in the mechanisms that maintain DNA fidelity. Recently, it has been discovered that the mutation frequency may rise significantly when the microbe is subjected to conditions of stress, particularly nutritional stress, which can occur on nutrient exhaustion. The phenomenon has been termed adaptive mutation and can, in part, be attributed to limitation of DNA mismatch repair in stationary phase culture (Notley-McRobb et al. 2003; Rosenberg 1997).

Site-directed mutation

Until the advent of gene cloning, the introduction of mutations into a particular gene was a strictly random process; mutant alleles could be selected or identified, but the location of the mutation could not be controlled. Now, by exploiting DNA synthesis in vitro, a technique known as polymerase chain reaction (PCR) (Mullis et al. 1986; Palmer 2004, see McPherson and Møller 2000 for a more detailed exposition), mutations can be targeted precisely to any base pair that is desired (Primrose et al. 2001), so as to introduce a missense, nonsense, or frameshift mutation. Introduction of a specific macrolesion is also possible. DNA synthesis requires DNA polymerase, a template, deoxyribonucleotide triphosphates, and a priming sequence. In the cell this is usually a short RNA sequence but, in vitro, synthetic oligodeoxyribonucleotide primers of approximately 20 nucleotides are used instead. The gene to be mutated is often cloned into a suitable cloning vector. The construct constitutes the template DNA for the in vitro synthesis. Vectors based on the genome of bacteriophage M13, which is a circular, single-stranded DNA molecule, were initially favored, because the recovery of single-stranded DNA for the reaction is greatly facilitated, in that phage particles contain only one DNA strand (Zoller and Smith 1982). Now, however, the technology is much improved and site-directed mutation is routinely achieved using genes cloned in standard plasmid cloning vectors, or using PCR products.

With M13 based cloning vectors, the primer used is complementary to the sequence at the prospective site of mutation. By incorporating a mismatch into the primer, a targeted mutation can be engineered into the gene of interest. The primer is extended by the DNA polymerase, using the circular single-stranded DNA molecule recovered from phage particles as template until the 5′ end of the primer is encountered, when the newly synthesized DNA circle is closed by DNA ligase, generating a double-stranded DNA replicon with a mismatched nucleotide base pair. When introduced into a suitable bacterial host by transformation, this hybrid molecule is replicated to yield one daughter molecule carrying the original allele of the gene of interest and one carrying the mutant allele. Further replication amplifies both versions of the gene. The plasmids can then be isolated as a mixture and used to transform the same or another suitable host to yield clones carrying one or other of the two recombinant replicons. Clones carrying the mutant gene are identified and separated from transformants with the original allele of the gene of interest. The former clones can then be cultured to provide the mutant gene in quantity. The gene is then resequenced to ensure that the desired mutation is the only one that has been introduced. By using a set of primers, each with a different, but deliberately designed, mismatch in the reaction, a set of mutants with mutations directed to particular nucleotides can be generated. This allows a region of a gene, or indeed the entire gene if so desired, to be subjected to systematic mutation for structure–function studies of the gene product or for analysis of the sequences controlling gene expression. Various modifications of this procedure, designed to make it more efficient and to optimize recovery of the desired mutant, have been developed (see Watson et al. 1992, for simple descriptions)

A multistage PCR method for site-directed mutagenesis now more commonly employed uses double-stranded DNA as template (Figure 5) (see also

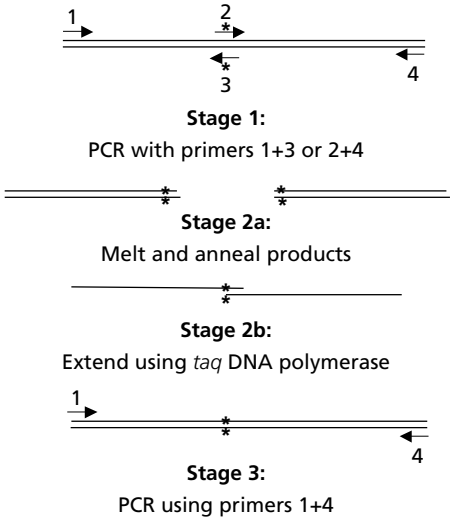

Figure 5 *Schematic representation of PCR site-directed mutagenesis. In stage 1, two separate PCR reactions are used to generate, from the template sequence, two linear, overlapping fragments having a mutation in the overlapping region – with the mutation being the result of primers partially mismatched with their target sequence (noted as stars). In stage 2, the two fragments are melted, mixed, and allowed to anneal to each other. This product is then used as a template for further PCR. The resulting product will comprise copies of the gene of interest with the desired mutation (shown on the diagram).*

Primrose et al. 2001). To begin with, the gene of interest is amplified as two, partly overlapping fragments (stage 1). One fragment is generated using a primer pair with the forward primer a perfect match and targeted to the start of the gene (primer 1) and the reverse primer targeted to the point of mutation and incorporating the desired mutation (primer 3). PCR amplifies a fragment with the mutation. A second fragment is generated in a similar fashion, but with the forward primer (primer 2, the complement of the reverse primer in the first reaction and so incorporating the mutation required) targeted to the point of mutation while the reverse primer (primer 4), perfectly matched to the gene sequence, is targeted to the end of the gene. PCR amplifies the second fragment, with the same mutation within the same sequence as on the first fragment. The two fragments are then mixed and used as a template in a third PCR reaction together with the forward primer from the first PCR reaction and the reverse primer from the second, i.e. primers 1 and 4 (stage 2). When the template is melted and then allowed to reanneal, a proportion of strands from the different fragments anneal across a short common region generating a DNA molecule with a short central double-stranded section (corresponding to the mutational primers in the two initial PCR reactions) and two long single-stranded tails. These then become templates to extend the short double stranded section of DNA in both directions to encompass the full gene. A PCR reaction then amplifies this product (stage 3), namely a full-length version of the mutant gene of interest. This is then recovered by ligation into a suitable cloning vector, where the mutant gene can either be examined directly, or used to mutate the original allele in the strain of origin by allelic replacement. For an up-to-date discussion of in vitro mutagenesis see Braman (2002).

Flip-flop mechanisms

Some functions expressed by bacteria and bacteriophages undergo changes that at first sight appear to be mutations. However, the basis of the changes is more like the operation of a switch than a random change in the DNA. Such changes occur as a result of site-specific recombination mechanisms that invert specific DNA sequences, the consequence of which is to turn off expression of one gene(s) and activate that of an alternative gene(s) (Craig 1988; Nash 1996). Two particularly well characterized systems, encoded by bacteriophages Mu and P1, operate to control the bacterial host ranges of the phages by controlling the production of alternative tail fibers for the phages (Giphart-Gassler et al. 1982). In *Salmonella* Typhimurium flagellar antigen phase variation, which allows the bacterium to evade the immune response of an infected host, is controlled by a very similar DNA inversion mechanism. Two genes, *H1* and *H2*, code for different forms of flagellin. Both proteins can polymerize to produce the cell's flagella. The cell can alternate expression of these two genes by inverting a short segment of the chromosome (Zieg et al. 1977). In phase I, flagellin encoded by *H1* is produced. In phase II, *H2*-encoded flagellin is synthesized and a gene called *rhI* is activated. The product of *rh1* is a transcriptional repressor of *H1*, so that production of flagellin encoded by *H1* is switched off. Hence, expression of *H1* and *H2* is mutually exclusive. The recombination inverts an approximate 1 kb sequence. In phase II orientation, the invertible sequence provides a promoter for *H2* and *rhI*. The sequence also encodes a gene called *hin*, the product of which mediates the inversion. The *hin* gene shows considerable homology with both *gin* and *cin*, the site-specific recombinase genes of bacteriophages Mu and P1, respectively, that mediate host specificity. The products of these three genes are functionally interchangeable.

Each of these three systems operates infrequently, the probability of inversion being about 10^{-8} per cell per generation. However, this low frequency is sufficient, within a population of cells or bacteriophages, to significantly extend the versatility of the organism. The ability of *S.* Typhimurium to switch flagellin production confers some protection against the immune response, whereas the ability to produce two sets of tail fibers broadens the host ranges of both Mu and P1, each set of tail fibers permitting infection of particular bacterial strains.

Other examples of phase variation controlled by invertible DNA segments are *E. coli* type I fimbriae (pili) (Abraham et al. 1985) and the fimbriae of *Moraxella bovis* (Marrs et al. 1988).

MOBILE GENETIC ELEMENTS

Insertion sequences and transposons

In the 1960s, evidence accumulated for the existence of a hitherto undescribed form of mutation. The first examples recognized in bacteria were found by Lederberg, who in 1960 described an unusual class of Gal^- mutants in *E. coli*. They reverted to Gal^+ at frequencies of 10^{-6}–10^{-8}, but the reversion frequency was not enhanced by mutagenic treatments. These results indicated that the mutations were neither deletions nor classical point mutations (base substitutions or frameshifts). Further, when the mutation was in one of the first genes of a set it exerted an unusually strong polarity on expression of subsequent genes in the operon, virtually eliminating expression from them (unlike polar nonsense mutations that merely reduce expression of the distal genes). The new type of mutation was described as a strong polar mutation (Jordan et al. 1968). Molecular genetic analysis of these mutations, using λ*gal* transducing phages, demonstrated that the *gal* operons of the mutants contained extra DNA sequences; revertants to Gal^+ had lost the additional sequences. The conclusion from these studies was that the mutations were generated by the insertion of extra pieces of DNA, called insertion sequence (IS) elements (Jordan et al. 1968), at the point of mutation. IS elements are now known to be but one type of a class of genetic elements called transposable elements. The one characteristic that all such elements possess is the ability to transpose, i.e. they can insert into different sites, usually unrelated, on the same or on different DNA molecules. Unlike host-mediated homologous recombination, transposition requires no homology between the transposable element and its sites of insertion, and the mechanisms are independent of the *recA*+ gene product of the bacterial host.

Since the initial discovery of IS*1*, IS*2*, and IS*3* (Fiant et al. 1972) in *E. coli*, many IS elements have been described from a wide variety of bacteria (Galas and Chandler 1989; Chandler and Mahillon 2002). They are common in bacterial plasmids and are normal components of many, if not all, bacterial chromosomes. They are also cryptic, in the sense that they do not confer on the host bacterium a predictable phenotype. In the past, their presence was usually indicated by mutation, i.e. the genetic damage they cause. More recently, however, many elements have been discovered as a result of bacterial genome sequencing (Chandler and Mahillon 2002).

In 1974, the discovery of a second type of transposable element, one that encoded a recognizable gene product, the TEM-2 β-lactamase determining resistance to several β-lactam antibiotics, including ampicillin (see Chapter 18, Antibacterial therapy), was reported by Hedges and Jacob (1974). It was termed a transposon, and many others carrying various resistance and other genes have since been identified and analyzed (see Berg and Howe 1989; Craig et al. 2002). Because of the ability of transposable elements to insert into a large number of sites, both on the bacterial chromosome and on plasmids, they assumed the popular name of 'jumping genes.' A few of these elements are described in Table 1.

It is now clear that there are several types of transposable element (see Craig et al. 2002). IS elements are generally small (1–2 kb) and encode only those functions needed for their own transposition, whereas transposons are larger, usually 4–25 kb (although considerably larger elements have been described), and they encode at least one function unconnected to transposition that alters the cell phenotype predictably (e.g. by conferring a particular antibiotic resistance). In addition, there are some bacteriophages, such as Mu and D108, that exploit transposition in their life cycles (Toussaint and Résibois 1983).

Bacteriophage Mu, mentioned earlier in relation to its site-specific recombination system, resembles a transposable element in that it inserts more or less at random into many different sites in the *E. coli* chromosome, as a consequence of its mode of replication; hence its name, Mu (for mutator phage). It is now known that phage Mu is a large transposable element that uses one form of transposition for replication.

Because transposition involves the movement of DNA sequences from one site to another, it is clear that whatever the mechanism, it is, by definition, a recombination event. Such events may be referred to as illegitimate recombination, to indicate that they occur independently of a classical recombination system and do not require extensive sequence homology between the sequences involved in the recombination.

The majority of known IS elements have a similar structure, namely a unique central sequence, comprising most of the element, flanked by short perfect or near-perfect inverted repeat (IR) sequences. Terminal IR sequences differ, both in sequence and size, from one element to another (c. 10–40 bp) (Table 1). For those elements that have been analyzed in detail, the unique central section encodes an element-specific transposition function(s). The IR sequences delineate the element, serving as specific sites for recombination mediated by the transposition enzyme(s). The inverted character of the terminal repeats and the asymmetric nature of the sequence ensures that both are retained in the transposed structure, i.e. the same sequence is recognized at both ends of the element and the DNA is cleaved at the same end of the IR sequence in both cases, i.e. precisely at the IS element–host replicon junctions.

Most transposons can be assigned to one of two broad groups, called composite transposons and complex trans-

Table 1 *Some transposable elements in bacteria*

Transposable element	Size (kb)	Terminal[a] repeats (bp)	Target size[b] (bp)	Phenotype[c] conferred	Origin
Insertion sequences					
IS*1*	0.768	18/23	9	None	Gram −ve
IS*2*	1.331	32/41	5	None	Gram −ve
IS*3*	1.258	32/38	3/4	None	Gram −ve

a) The number of identical base pairs in both terminal repeats/size of terminal repeats. DR, direct repeat; inverted repeat.
b) The size of the direct duplications which are found to flank the transposon in situ.
c) Entries which relate to an antibiotic(s) refer to resistance to that drug(s). Ap, ampicillin; Cm, chloramphenicol; Ery, erythromycin; Gm, gentamicin; Hg, mercuric ions; Km, kanamycin; Mec, methicillin; Sm, streptomycin; Sp, spectinomycin; Su, sulfonamide; Lac, lactose metabolism; Tb, tobramycin; Tc, tetracycline; Tp, trimethoprim. Sm/Sp indicates resistance to both antibiotics conferred by the same modifying enzyme.
d) Heat-stable toxin produced by some enterotoxigenic strains of *Escherichia coli*.
e) See text. nd, not determined.

posons. Composite transposons, as their name implies, are constructed from recognizable simpler units. Their overall form comprises a unique central sequence that encodes the function(s) by which the element is recognized and which lacks transposition functions, flanked by long sequence repeats (1–2 kb) which are arranged as direct repeats or, more commonly, as IRs. These terminal repeats provide transposition functions and, in all cases examined so far, comprise a pair of IS elements. The more common inverted arrangement possibly reflects the fact that it confers greater stability (coherence) on the composite structure than direct repeats where deletion of the transposon's distinguishing feature(s) as the result of recombination between the terminal IS elements, mediated by the host's homologous recombination machinery, is an ever-present possibility (Figure 4).

Complex transposons do not have modular structures. Rather, both transposition and non-transposition functions are located in the bulk of the sequence which is flanked by short (c. 40 bp) terminal IRs. Indeed, complex transposons resemble enlarged IS elements rather than composite transposons. The first transposon identified, Tn*1* (formerly Tn*A*; Hedges and Jacob 1974), typifies this type of element. Its structure is illustrated in Figure 7, p. 94. Tn*1* is one of a family of transposons that are ancestrally related in terms of their transposition functions. This was first recognized because of striking similarities between their IRs. Subsequently, more extensive sequence analysis of several of these

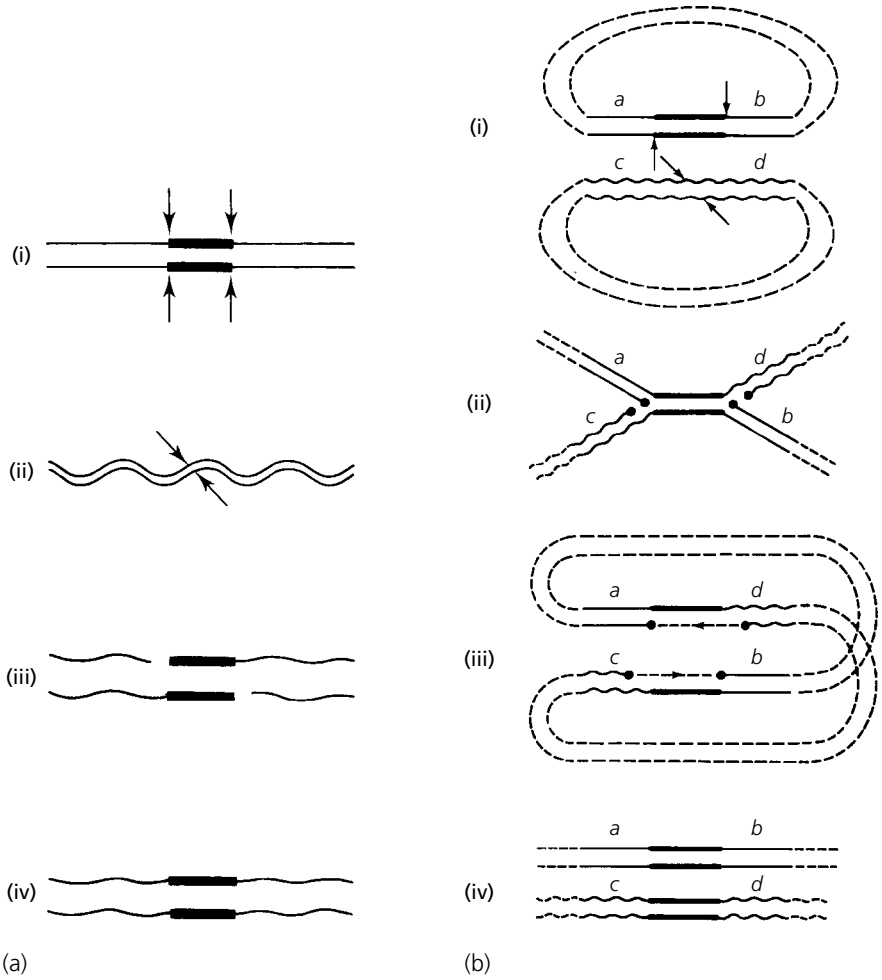

Figure 6 *Models for transposition.* **(a)** *Conservative transposition. (i) Flush double-stranded cuts (vertical arrows) are made at the ends of the transposable element (bold lines) and a staggered cut (diagonal arrows) is made at the target site. (ii) One end of the transposable element is attached by a single strand to each protruding strand at the staggered cut to insert the transposable element into the target site. (iii) Two small gaps, generated as the consequence of the staggered cut, are left on opposite strands, one at each end of the element. (iv) The gaps are filled in by DNA repair synthesis to produce short direct repeats that flank the transposable element.* **(b)** *Replicative transposition. (i) Single-stranded cuts are made at the ends of the transposable element, and a staggered cut of opposite polarity is made in the target DNA. (ii) One end of the transposable element is attached by a single strand to each protruding end of the staggered cut. Two replication forks are thus created, and replication may proceed to copy the transposable element. (iii) Semi-conservative replication has generated two new transposable elements from the original element and a short direct repeat of the target site. If* ab *and* cd *were circles,* a, b, c, *and* d *would now be covalently connected and transposable elements would form the joint regions of a fused replicon. (iv) A site-specific crossover between the transposable elements would resolve the cointegrate into the starting replicon* ab *and the target replicon* cd*, which now has a copy of the transposable element flanked by short direct repeats of the site of insertion (Shapiro 1979).*

elements demonstrated that the entire transposition mechanism of one is related to that of the others. In some cases the evolutionary divergence is small, so that the transposition functions are interchangeable. In other instances, elements are more distant in terms of evolution and analogous functions cannot be interchanged (Sherratt 1989; Grinsted et al. 1990; see also Craig et al. 2002)

Transposable elements have been grouped according to their similarities. Accordingly, IS elements and composite transposons are called class 1 transposable elements, whereas Tn*1* and related transposons are called class 2 transposable elements. Class 3 accommodates the transposing bacteriophages such as Mu. Finally, class 4 at present accommodates those elements that do not naturally fall within classes 1–3. Perhaps two of the best known are Tn*7*, a compound transposon encoding resistance to trimethoprim and streptomycin prevalent in gram-negative bacteria, particularly the Enterobacteriaceae, and Tn*916*, an unusual transposon from *Enterococcus faecalis* that encodes resistance to tetracycline and which is conjugative, i.e. can mediate its transfer not only from one replicon to another by transposition, but also from one bacterial cell to another by a form of conjugation (Salyers et al. 1995). Tn*916* (Franke and Clewell

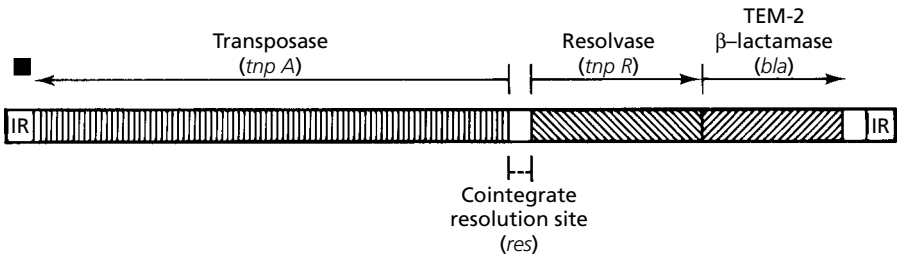

Figure 7 *Map of Tn*1 *showing the location of its three genes. The arrows indicate the direction of transcription. The cointegrate resolution site (*res*) is necessary for resolution of cointegrates, by resolvase, during transposition (see Figure 6). IR, perfect 38 bp inverted repeats*

1981) serves as the archytype for this kind of transposable element. Transposons with conjugative properties have also been found in *Bacteroides* spp. (Salyers and Shoemaker 1995), and, more recently, elements originally thought to be plasmids because they mediate transfer of antibiotic resistance genes between members of the Enterobacteriaceae are now considered to be conjugative transposons (Böltner and Osborn 2004).

Transposable elements not only mediate their own genetic mobility, but can be instrumental in bringing about important rearrangements in DNA molecules. Not only do they provide useful genes, but their transposition activities can generate macrolesions such as deletions, duplications, and inversions. Because many of them insert into DNA molecules more or less at random, they can generate mutation by disrupting the sequence continuity of genes; indeed, it was this consequence that first brought IS elements to the attention of bacterial geneticists. That the insertions are often polar has been noted for IS elements; this is also true for transposons. In addition, they can, in the cases of particular elements, activate previously silent genes by inserting upstream and adjacent to the gene to provide a functional promoter (Jaurin and Normark 1983; Pilacinski et al. 1977; Wood and Konisky 1985; Rasmussen and Kovacs 1991; Podglajen et al. 1994; Chandler and Mahillon 2002). The polar effects of transposable element insertion arise because the elements are, in general, self-contained and encode translational and transcriptional terminators that prevent transcription proceeding far into the element across the junction of the element and the adjacent host DNA. Thus the genes of an operon which are promoter distal to an insertion are separated from their promoter and normally become silent. Only when there is a promoter at the end of the element nearest to the orphan genes that can direct transcription towards that end of the element and beyond, are the remaining genes of the operon (downstream of the insertion) expressed.

IS*2* exerts strong polar effects when in one of its two possible orientations (this was how it was discovered). In this orientation (designated orientation I), a rho-dependent transcription termination site prevents transcription proceeding through the element into adjacent sequences. In the opposite orientation (orientation II), IS*2* can provide a promoter sequence that can switch on downstream genes (Saedler and Reif 1974). Mutations in wild-type IS*2* that create promoters have also been described (Sommer and Saedler 1979). It is of interest to note that cloned genes, either not expressed or expressed poorly from an original construct, may be activated by insertion of a transposable element upstream from them. However, it should be noted that this aspect of transposable element activity appears to be restricted to a minority of specific elements, of which IS*2* is one.

Specificity and mechanism of insertion

When transposable elements insert into new sites, short duplications of recipient DNA sequence are usually generated. These direct repeats, commonly 5 or 9 bp (Table 1), flank the transposable sequence. The size of the duplication is specific to the element. The duplications arise because the recipient DNA at the target site is cleaved across both its strands as a short staggered cut. The transposon is inserted by joining it to the short single-strand extensions created by the cleavage. This generates small single-stranded gaps, on opposite strands, in the recipient DNA at the ends of the element. These gaps are filled in, probably by DNA gap repair synthesis (Sancar 1996) to generate the short flanking duplication. So typical is this arrangement that if, when analyzing a new bacterial nucleotide sequence, a section of DNA is found to be delimited by short IRs and flanked by short direct repeats (DR) then it is immediately considered likely to be a transposable element.

A wide range of insertion specificities has been found for different transposons and some display different characteristics with different DNA molecules. Some (e.g. Tn*1*) insert at many places on different plasmids and into the bacterial chromosome with little recognizable specificity save, perhaps, a preference for AT-rich regions; others appear to be rather more specific, e.g. IS*4* has been found to insert into only one position in the *gal* region of the *E. coli* chromosome. Although

Tn*10* inserts at many different sites, they are all related to the 9 bp consensus sequence, NGCTNAGCN (where N denotes any base). The more closely a site approximates to this sequence the more readily it is used as a site of Tn*10* insertion. The preference for AT-rich regions shown by some transposons suggests that the transposition mechanism used may involve a degree of strand separation at the target, since AT bps are inherently more easily disrupted than GC bps.

Initially, research workers sought to describe transposition in terms of a single mechanism. It is now clear that this notion was misconceived and that there are several different mechanisms. Three fundamentally different strategies have been reported. One, used by several IS elements and their composite transposons, is called conservative, or cut-and-paste, transposition (Figure 6a). In this, the transposable element is cut from the donor DNA as a discrete double-stranded section of DNA with flush ends. The free ends are ligated to the target site using the single strand extensions generated by the staggered cut at the target site. The small gaps that remain are filled in to generate the direct flanking repeats typical of IS element insertions. In this mechanism the entire transposable sequence on one DNA molecule is moved to another DNA molecule (Bolland and Kleckner 1996). It is believed that the donor molecule minus the transposon is degraded (Berg 1989; Kleckner 1989). Some transposons, e.g. Tn*7*, use a variation of the cut-and-paste transposition system (Sarnovsky et al. 1996). Others, e.g. conjugative transposons, are excised from the donor site to generate a circular form of the element. This entity then either inserts into another site on the same or on another replicon in the same cell, or it transfers, by conjugation, to another cell where it is inserted into one of the resident replicons (Salyers et al. 1995). Although these elements display features of a bacterial plasmid, they differ from a plasmid in that they lack their own replication system. They are replicated passively as components of the replicons into which they insert.

A second mechanism of transposition involves semiconservative DNA replication. This was realized when it was found that certain mutants of Tn*1* generated end products that differed from those of the parental transposon. With these mutants, the end product of a transposition from one replicon to another was a cointegrate – a recombinant DNA molecule comprising both the donor and the recipient replicons with directly repeated copies of Tn*1* at the plasmid junctions, i.e. the transposon had been replicated (Figure 6b). These recombinants could then break down in a *rec*$^+$ host, via normal recombination, to yield a replicon indistinguishable from the original plasmid donor and a transposon-carrying derivative of the recipient plasmid, i.e. a product indistinguishable from that generated by the parental transposon. Shapiro (1979) and Arthur and Sherratt (1979) synthesized these observations, and others involving bacteriophage Mu, into the now generally accepted model of replicative transposition (Figure 6b).

For some IS elements a small proportion of transposition events appear to occur via replicative rather than conservative transposition. This observation has been taken to imply that the two forms represent a split pathway proceeding from a common start (Ohtsubo et al. 1981). Consistent with this interpretation is the observation that c. 5 percent of transpositions of Tn*1* appear to be by a direct pathway rather than by replicative transposition (Bennett et al. 1983).

More recently, it has been discovered that members of a novel class of IS elements, of which IS*91* is the type element (Mendiola et al. 1992), and that lack terminal IR sequences, transpose by a third mechanism, RC transposition, that involves a form of rolling circle replication. Insertion is also site-specific, although the target site is small, 4 bp. The transposases of these elements are related to the initiator proteins of certain plasmids of *Staphylococcus aureus* (although the IS elements were isolated from gram-negative bacteria) (Mendiola and de la Cruz 1992). The plasmids replicate via a rolling circle mechanism that generates a single-strand version of the plasmid which is then converted to the double-stranded form. It is likely that this family of IS elements transposes by a mechanism that involves a single-stranded, possibly circular intermediate (Tavakoli et al. 2000; Garcillán-Barcia et al. 2002).

Deletions, duplications, and insertions

Deletion induced by a transposable element was first seen for IS*1*. In the *E. coli* chromosome, the frequency of deletions near a copy of IS*1* was found to be 100- to 1 000-fold higher than that observed elsewhere (Reif and Saedler 1975). Subsequently, other elements and transposons were also shown to stimulate the frequency of deletions in their vicinity. Several studies have demonstrated that the deletions always extend precisely from one end of the particular transposable element, leaving the element itself intact but removing one copy of the direct repeats that originally flanked it. Deletions such as these can, in principle, be formed in one of two ways. First, a second copy of the transposable element can insert into a different position on the same replicon, but in the same orientation as the first. Host-mediated recombination can then occur between the copies, effectively deleting one copy and the intervening DNA sequence (see Figure 4). Second, an element may transpose intramolecularly to a nearby site on the same DNA molecule by replicative transposition. If the insertion at the new site assumes the same orientation as that at the first site, the result is an automatic deletion of one of the copies of the element and the DNA sequences between the original site and the new site of insertion (Arthur and Sherratt 1979; Craig 1996).

DNA inversions may also arise by one of two mechanisms. Following insertion of a second copy of a transposable element into a DNA sequence to generate an inverted repeat, a single host-mediated recombination event across the repeated sequences will invert the intervening sequence (see Figure 4). Alternatively, when an element transposes intramolecularly by replicative transposition to a new site on the same DNA molecule in such a manner as to generate inverted repeats of the element, the intervening sequence between the old and new sites of insertion is automatically inverted, again as a consequence of the mechanics of the transposition (Arthur and Sherratt 1979). In practice, after the event, it is impossible to determine which mechanism generated a particular inversion because extended IRs act as recombination loci periodically to invert and reinvert the intervening sequence. As noted earlier, a similar phenomenon is exploited in the site-specific recombination systems that control P1 and Mu phage host ranges and *S.* Typhimurium flagellar type.

Transposition functions

Several transposons have now been studied in detail and, with very few exceptions, each element encodes its own transposition functions (see Craig et al. 2002). Perhaps the best studied to date is Tn*3* (which is virtually identical to Tn*1*), the class II element that confers resistance to a range of penicillins, including ampicillin and carbenicillin. The element is 5 kb and encodes three proteins: a TEM β-lactamase and two proteins that are necessary for transposition (see Figure 7). The larger of these, called transposase, is encoded by *tnpA* and is indispensable; it mediates cointegrate formation (Figure 6b). The second transposition enzyme, resolvase (encoded by *tnpR*), is normally responsible for resolution of the cointegrate to release the final transposition product. The promoters for both genes are located in the length of c. 100 bp that separates them. The site at which resolvase acts is called the *res* site, also located in the intergenic region between *tnpA* and *tnpR* (Sherratt 1989). A consequence of mutations in *tnpR* is that the frequency of transposition increases by approximately two orders of magnitude, i.e. resolvase functions not only as a site-specific recombination enzyme but also as a transcriptional repressor. This duality indicates a more general feature of prokaryotes that seems to be emerging, namely optimization of the genome. It is not uncommon to find the same DNA sequence performing more than one function.

In a *rec*$^+$ host (Watson et al. 1987), cointegrate resolution can be effected by the host's own recombination system, since the two copies of the element in the cointegrate are direct repeats and provide extensive sequence homology. Hence, *tnpR* mutants of Tn*3* generate cointegrates that are relatively stable in a recombination-deficient host, e.g. one which is *recA*, whereas normal transposition products are generated in a recombination-proficient host. Analyses of other class II transposons, e.g. γδ (Tn*1000*), Tn*21*, *Tn501*, and Tn*1721* (see Table 1), have shown that each encodes a transposase and a resolvase of approximately the same sizes as those of Tn*3*. The transposases are phylogenetically related, as are the resolvases. Some of these analogous enzymes are functionally interchangeable but others are not, indicating different degrees of evolutionary proximity (Grinsted et al. 1990).

Well-studied class I elements are IS*1*, IS*10* (Tn*10*), IS*50* (Tn*5*), and IS*903* (Tn*903*) (see Table 1). Each is genetically distinct and encodes its own unique transposition functions. The transposition of each is also regulated, but the strategies of regulation differ from one element to another. Thus IS*10* regulates both transcription and translation of its single transposition gene, whereas IS*50* regulates transcription of its transposition gene and modulates the activity of the enzyme with another IS*50*-encoded protein (Berg 1989; Kleckner 1989). Bacteriophage Mu, as might be expected of a lysogenic phage, has a variety of control systems to regulate its transposition (i.e. replication) activity (Toussaint and Résibois 1983), which is essentially dependent on a single phage gene designated *A*.

Not all transposition systems have so few element-encoded transposition functions. Tn*7*, for example, has five transposition genes, three of which are needed for all transposition events. Tn*7* displays two types of transpositional behavior. It can insert, more or less at random, into many different sites on plasmids at a relatively low frequency but it can also insert into one specific site on the *E. coli* chromosome at high frequency. Which transposition event occurs is determined by which one of the other two functions is used in the reaction (Craig 1989; Sarnovsky et al. 1996).

In addition to element-encoded functions and irrespective of the transposition mechanism, host functions are also required, such as DNA polymerase and DNA ligase activities. Several others have also been implicated.

Ubiquity of insertion sequences

The importance of insertion sequences and transposons in mediating bacterial variation cannot be overstated. Not only can they add useful genes to an organism directly (e.g. antibiotic resistance) but also, because of their ability to operate in pairs to transpose otherwise non-transposable genes (e.g. the unique central sequences of class I transposons), they can, in principle, effect the transposition of any bacterial DNA sequence from one DNA molecule to another. Indeed, IS elements have been instrumental in mobilizing chromosomal β-lactamase genes, such as the *blaSHV* of *Klebsiella pneumoniae* (Ford and Avison 2004) and the

blaCTX-M genes of *Kluyvera* spp. (Walther-Rasmussen and Hoiby 2002) on to plasmids which have then carried these genes into *E. coli* and other Enterobacteria. These types of elements are not restricted to prokaryotes; indeed, the first reports of transposable elements in higher organisms, specifically maize, preceded description of those in *E. coli* by 10–15 years (McClintock 1953). Transposable elements are now known to exist in a number of eukaryotes, including yeast and *Drosophila* (see Shapiro 1983; Berg and Howe 1989; Craig et al. 2002).

Mutation by transposon insertion

Because of their ability to insert into replicons almost at random, transposons have been exploited as mutagens. They possess the advantage over other random forms of mutation that the site of mutation is grossly altered by the addition of new DNA sequences, which can be physically mapped by restriction enzyme analysis or by sequencing. Because of this, artificial transposons with a range of properties have been created from natural ones to provide tools to facilitate molecular genetic investigations (Berg et al. 1989; de Lorenzo et al. 1990).

Transposon mutagenesis has been adapted in an ingenious way to generate mutations in bacterial virulence genes (Hensel et al. 1995) and to allow negative selection. This technique, signature tagged mutagenesis (STM), is a negative selection method for bacterial virulence gene identification based on the ability to follow, simultaneously, the fates of many different mutants within a single animal. Individual copies of a transposon (mini-Tn*5*, de Lorenzo et al. 1990) were tagged with small, unique nucleotide sequences. The identity of any particular copy of the transposon could then be determined readily by hybridization techniques. These tagged transposons were then used to generate a bank of 1 510 random transposon mutants in a strain of *S.* Typhimurium. Each isolate in the bank was checked to confirm that it had acquired a uniquely tagged copy of the mini-Tn*5*, yielding a slightly smaller bank of 1 152 mutants. Cultures of each isolate were grown in the wells of microtitration trays and 12 mixtures, each with 96 strains, were prepared and used to inoculate BALB/c mice by intraperitoneal injection. Three days later, the mice were killed and the bacteria were recovered from each mouse by plating spleen homogenates onto a suitable medium. Approximately 10 000 colonies recovered from each mouse were pooled and the total DNA was extracted. The transposon tags were amplified and labeled by PCR and colony blots of the original 96 mutants in the subset were probed. The results were compared with the hybridization pattern obtained with a 'tag probe' obtained with DNA from the mixed inoculum of 96 mutants. Colonies which probed positive in the control, but not with the probe prepared from DNA from cells post-passage through mice, were shown to have had a virulence gene inactivated by the mini-Tn*5*. Because these strains were less virulent they survived less well in the mouse and so were poorly recovered from the spleen of the infected animals, in turn giving a much reduced yield of that particular transposon tag in the DNA used to prepare the 'tag probe.' Forty virulence mutants were identified in the bank of 1 152. Among these mutants, approximately half were in genes known to be involved in virulence. The remainder constitute a set of new virulence or colonization survival genes. These results accord well with an estimate of approximately 150 virulence genes in *S.* Typhimurium (Groisman and Saier 1990), of which more than half have been identified.

Integrons and gene cassettes

In addition to plasmids and transposable elements, bacteria have yet other systems for gene dissemination, namely, integrons (Stokes and Hall 1989; Bennett 1999). Integrons are essentially site-specific recombination systems that mediate the movement of small DNA elements called gene cassettes. Most of the gene cassettes described carry a single resistance gene. About 60 antibiotic resistance genes, including those for resistance to aminoglycosides, β-lactams, chloramphenicol, erythromycin, sulfonamides, tetracycline, and trimethoprim have been identified as being on gene cassettes (Recchia and Hall 1995). The most recently identified antibiotic resistance gene cassettes encode the metallo-β-lactamases IMP and VIM (Laraki et al. 1999; Lauretti et al. 1999; Poirel et al. 2000; Riccio et al. 2000; Nordmann and Poirel 2002), encoding resistance to the potent carbapenem β-lactams imipenem and meropenem.

Integrons were first identified on Tn*21* and closely related transposons (Grinsted et al. 1990), but are now known to be more widely distributed (Hall and Collis 1995). Molecular analysis of the resistance genes of Tn*21* and related elements revealed that although different transposons carried different complements of resistance genes, most appeared to be accommodated at a single point on the basic structure, i.e. irrespective of the identity of the resistance gene(s) carried on a particular transposon, the sequences flanking the gene or gene cluster were the same, called the 3′- and 5′-conserved regions. Analysis of the 5′-conserved region revealed a gene, *int*, encoding a protein of the 'integrase' family. This enzyme, called integrase, is a site-specific recombinase. Beside *int* is *attI*, a site that is recognized and utilized by the integrase to capture gene cassettes. The essential components of an integron, located in the 5′-conserved region, are an *int* gene, an *attI* site, and a promoter in the correct orientation to express the genes on captured cassettes, because most cassette genes identified to date lack their own promoters. Within the

3′-conserved region is often found the *sul1* gene, encoding resistance to sulfonamides. These integrons are called type 1 integrons (Hall and Collis 1995). Integrons are classified according to their integrase genes (Hansson et al. 2002; Collis et al. 2002). Members of the same class have closely related integrase genes.

A gene cassette can exist in two forms:

1. as a linear insert within an integron, or
2. transiently as a small double-stranded circle of DNA carrying one (or occasionally two) resistance genes and a recombination site called a 59-base element (Hall et al. 1991).

Integrase-mediated recombination between a 59-base element on a cassette and the *attI* site inserts the cassette gene(s) into the integron and orients it so that it is expressed from the integron promoter (Collis et al. 1993). Several cassettes may be captured in this way to form a resistance gene array in which each gene is separated from the next by a 59-base element. Arrays of five and six resistance genes have been found; 59-base pair elements do not have a unique sequence, but all conform to a consensus, which may be longer than 59 bases (Hall et al. 1991; Stokes et al. 1997).

Movement of gene cassettes is possible because the integration of a cassette into an integron is a reversible process, so what has been captured by one integron can subsequently be released and captured by another (Collis and Hall 1992). In this way the complement of resistance genes can be constantly rearranged and moved from one DNA molecule to another, providing it carries an integron or a suitable integration site.

In principle, there is no limit to the number of gene cassettes that can be incorporated into an integron, but functional constraints, such as reduced expression of genes located some distance from the integron promoter, may limit the number in practice. Nonetheless, class 1 integrons with eight gene cassettes have been reported (Naas et al. 2001), and super-integrons, with dozens of gene cassettes, reported first in *Vibrio cholerae* (Rowe-Magnus et al. 1999; Mazel et al. 1998) as a result of genome sequencing, have since been identified in a variety of bacteria (Nield et al. 2001; Rowe-Magnus et al. 2001; Vaisvila et al. 2001).

ACQUISITION OF NEW GENES

Genetic diversity in bacteria growing in monoculture in the laboratory can occur only by mutation, as described above. In mixed cultures, as are found in nature, diversity can be provided by the transfer of DNA from one cell to another, provided that the new genes can be stably inherited by the progeny of the transcipient cell. Four mechanisms of gene transfer have been described for bacteria, although not all necessarily apply to a particular bacterial species or strain; these are transformation, transduction, conjugation, and cell–cell fusion.

Genetic information (i.e. DNA) acquired by one of these four mechanisms is inherited, provided that one of two situations pertains; either the newly acquired DNA is incorporated into one of the replicons in the recipient cell by some form of recombination, or the newly introduced DNA is self-maintaining, i.e. is a replicon in its own right. In the former case, newly incorporated sequences are substituted for existing ones. The 'invading' DNA is usually linear and homologous to only part of the rescue replicon and is itself not a replicon. Homologous sequences on the acquired DNA and on the appropriate resident replicon (chromosome or plasmid) are efficiently paired and exchanged by recombination (Figure 8). DNA sequences not rescued by recombination are ultimately degraded. The mechanism is one of general recombination and requires that the host be recombination-proficient (Rec^+) (Smith 1988, 1989). In particular, the host must have a *recA*+ gene (Smith 1988), the product of which is essential for homologous recombination. In laboratory studies of this type, gene exchange often involves wild-type genes and their mutant alleles. For example, a length of DNA that includes the lactose fermentation genes (*lac*+) from *E. coli* K12 is introduced into a strain that cannot ferment lactose because of mutation in its *lac* operon. Recombination between the newly acquired chromosomal segment of DNA and the equivalent region on the chromosome of the recipient cell results in the substitution of the wild-type allele for the mutant allele and restoration of the recipient cell's ability to ferment lactose. Allelic variation is seen in naturally occurring bacteria, e.g. the genes that determine the antigens of *Salmonella*.

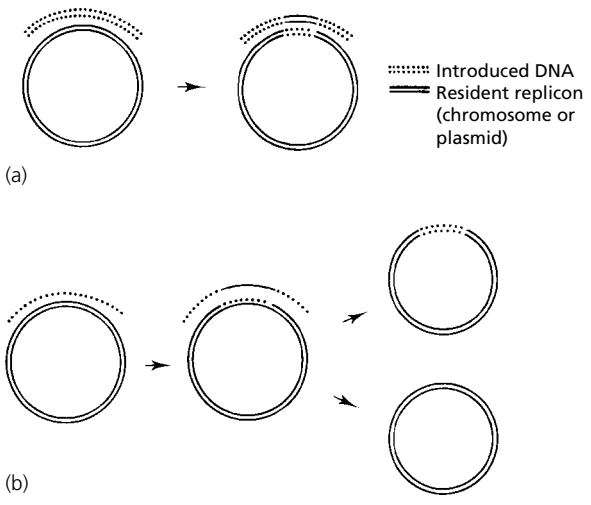

Figure 8 *General recombination. The figure shows two crossovers in homologous DNA having occurred between* **(a)** *two duplex molecules and* **(b)** *a single-stranded and a duplex molecule. Multiple crossovers (not illustrated) usually occur between homologous regions of DNA. The figure does not illustrate the mechanism of crossover. The RecA protein is required and some understanding of the mechanism is emerging (see text).*

When that part of the chromosome of *Salmonella* Paratyphi B that encodes antigen b is transferred into *S.* Typhimurium, recombination can lead to the substitution of the sequence encoding antigen b for the chromosomal sequence that encodes antigen i. In this way, new *Salmonella* serotypes are created. Phylogenetic relationships among Enterobacteriaceae have been reviewed by Sanderson (1976) (see also Chapter 51, The Enterobacteriacea: general characteristics).

DNA may also be added to the genome of the recipient cell. Plasmids (see next section, Plasmids) are autonomous DNA molecules and, to survive transfer, do not need to be rescued by recombination. Transposable elements, as discussed above, although not replicons, may insert into other DNA sequences with no requirement for homology or any loss of recipient DNA (although the insertion may result in loss of a particular function). Conjugative transposons, like plasmids, can transfer by conjugation from one bacterial cell to another, but unlike plasmids must integrate into one of the existing replicons in the new host to survive. Conjugative transposons belong to an extended group of mobile DNA elements called integrative conjugative elements (ICE) (Burrus et al. 2002) that includes elements originally thought to be plasmids (Osborn and Böltner 2002; Böltner and Osborn 2004) and the SXT resistance element of *Vibrio cholerae* (Hochhut et al. 2001; Beaber et al. 2002). In general, these elements integrate into particular sites on the host chromosome mediated by site-specific recombination mechanisms.

It is now known that all four mechanisms of gene transfer apply to both gram-positive and gram-negative bacteria, although not necessarily with any one particular bacterial strain. While some transfer systems that are widely used in the laboratory (e.g. transformation of *E. coli*) are likely to be laboratory artefacts rather than naturally occurring transfer systems, others (e.g. natural transformation of *Neisseria* spp. and *Streptococcus pneumoniae*) are known to have played important roles in gene modification and dissemination in nature (Dowson et al. 1994). For more information, see Grinsted and Bennett (1988).

Transformation

The first observation of bacterial transformation was by Griffith (1928) when studying pneumococcal infection in mice. The virulence of pneumococci depends on the capsular polysaccharide that gives the colonies a smooth appearance (S phenotype). Colonies of nonvirulent strains, without capsules, have a rough appearance (R phenotype). Griffith observed that when a mixture of living avirulent R cells and heat-killed virulent S cells was injected into mice, some of them died, whereas injection of either live R cells or heat-killed S cells was not lethal. From the dead animals, Griffith isolated virulent S cells whose capsular type was the same as that of the injected dead S cells. Griffith concluded that the heat-killed S cells had released something that had been taken up by the live R cells and had transformed them to the virulent S cell type. It was not until 1944 that Avery et al., using fractionated cell components, demonstrated that the transforming factor was DNA.

Cells that are able to take up DNA from their environment and incorporate it into the genome are said to be competent. In the case of some bacteria (e.g. *E. coli*), a state of competence can be developed by washing the cells with certain salt solutions (Saunders and Saunders 1988) but is otherwise absent. In others, competence is a natural feature of the life cycle as, for example, in the pneumococcus. Furthermore, some bacteria are competent at all times, whereas others display competence only at a particular phase of the growth cycle (Saunders and Saunders 1988). In the latter case, competence commonly develops towards the end of logarithmic growth in batch culture. Species that display natural, rather than laboratory-induced competence include *Acinetobacter calcoaceticus*, *Azotobacter vinelandii*, *Bacillus subtilis*, *Haemophilus influenzae*, *Moraxella* spp., *Neisseria* spp., *Pasteurella novicida*, some *Pseudomonas* spp., *Rhizobium* spp., *S. pneumoniae*, and *Xanthomonas phaseoi* (Lorenz and Wackernagel 1994). Species that can be made competent artificially, by one means or another, include *E. coli*, *Pseudomonas* spp., *S.* Typhimurium, and *S. aureus.*

Natural competence

Competence involves the ability to bind DNA to the cell surface and then transport it through the cell envelope into the cytoplasm prior to incorporation into the genome. The first of these activities, particularly in cases of natural competence, may involve specific cell receptors; this idea is supported by studies of interaction of competent pneumococci with DNA, in which the kinetics have been found to follow those of a classic enzyme–substrate reaction, and by the finding that new envelope proteins are synthesized as competence is acquired (Dubnau 1999).

The best characterized naturally occurring transformation systems are those of *S. pneumoniae*, *B. subtilis*, and *H. influenzae.* In all three systems, double-stranded donor DNA binds to the cell surface and is cut into discrete lengths giving fragments of 15–30 kb in the case of *B. subtilis*, 8–9 kb for *S. pneumoniae* and c. 18 kb for *H. influenzae*. The transforming activity of chromosomal DNA is better with large DNA fragments than with small, and there is a minimum size requirement for the donor DNA below which no transformation activity is seen. With *B. subtilis* and *S. pneumoniae* there is a period after DNA uptake during which the acquired DNA is incorporated into the genome. This period has been termed the eclipse phase.

B. subtilis and *S. pneumoniae* take up DNA from unrelated (heterospecific) bacteria as well as from closely related (homospecific) bacteria, whereas *H. influenzae* and *Neisseria gonorrhoeae* efficiently take up only homospecific DNA (Dubnau 1999). A membrane protein detectable only in competent *H. influenzae* and capable of binding DNA has been reported, and Sisco and Smith (1979) found that a specific nucleotide sequence of 8–12 bp mediates binding to the protein. It has been estimated that there are approximately 600 copies of this sequence on the *H. influenzae* chromosome, but it is rarely encountered on heterologous DNA. Such a specific mechanism is unlikely to have been preserved by chance, which implies that transformation plays an important role in the life-style of *H. influenzae*.

The fate of transformed donor DNA depends largely on its source. If the DNA is linear and homospecific, it can be incorporated into the chromosome of the recipient cell by recombination. If the linear DNA is heterospecific, its rescue will depend on whether there is sufficient homology with a resident replicon to permit recombination. Recombination with a resident replicon is not necessary when the donor DNA is itself a replicon, i.e. bacteriophage DNA (in which case the phenomenon is called transfection) or plasmid DNA. In these cases, however, successful transformation appears to require the uptake of more than one copy of the replicon, although complete duplication of sequence is not necessary. This finding indicates that replicon re-establishment also involves recombination (Saunders and Saunders 1988). In systems that rely on natural competence, transformation with homospecific chromosomal DNA is usually much more efficient than with intact heterospecific replicons, probably because of the requirement for sequence duplication to effect recombinational rescue, i.e. in the case of transformation with heterospecific DNA such as a plasmid, uptake of two plasmid molecules is necessary to provide the homology needed for recombinational rescue (unless the cell already contains a replicon with partial homology). Consistent with this interpretation is the finding that transformation with plasmid dimers (i.e. duplicate copies of the same plasmid joined head to tail in the same DNA molecule) is as efficient as transformation with homospecific chromosomal DNA (Saunders and Saunders 1988).

Artificial competence

The ability to transform bacteria is a valuable experimental tool but several commonly used laboratory bacteria (e.g. *E. coli*, *Pseudomonas putida*, *S.* Typhimurium, and *S. aureus*) do not display transformation competence at any stage of their life cycles in laboratory culture. Therefore, methods have been devised that can induce artificial competence. The common feature of these methods is the treatment of bacteria with salt solutions at 0°C. The most commonly used salt is calcium chloride (Saunders and Saunders 1988). The method was first developed to enable *E. coli* to take up noninfective phage DNA, and has since been used extensively to introduce plasmid DNA.

These transformation systems appear to work best with plasmid or bacteriophage DNA, rather than with chromosomal DNA. Indeed, *E. coli* does not transform efficiently with chromosomal DNA unless it is deficient in exonuclease V (encoded by the *recBCD* genes), since this enzyme degrades invading linear DNA; in addition, the cell must also be mutated at another locus, *sbcB*. This mutation restores recombination proficiency which is lost by mutations at *recB* and *recC*. Recombination is necessary to rescue linear homospecific DNA sequences.

Transformation with artificial competence works most efficiently with covalently closed circular (ccc) DNA, i.e. intact replicons such as bacteriophage genomes and plasmids (Cohen et al. 1972). These double-stranded DNA molecules are taken up intact and incorporated efficiently into the genome as autonomous replicating units. Any damage to the ccc form reduces the efficiency of transformation, as does increasing the size of the replicon; small plasmids transform the cell at much higher frequencies than large plasmids. It should be noted that induction of artificial competence is bacterial species-specific. Although very efficient systems have been developed for particular laboratory strains of a particular organism, these systems often do not work efficiently with other types of bacteria, or even with natural isolates of the same bacterium.

DNA may also be induced to enter bacterial cells when cell suspensions are mixed with free DNA and are subject to electrical discharge through the suspension, a procedure termed electroporation (or electrotransformation) (Miller 1994). This is now a commonly used method to introduce DNA molecules into many different bacterial species and electroporation apparatus is readily available commercially.

Conjugation

'Conjugation' is the term used to describe the transfer of DNA directly from one bacterial cell to another by a mechanism that requires cell-to-cell contact. DNA is transferred in a nuclease-resistant form that distinguishes the mechanism from transformation and without the aid of a bacteriophage, which distinguishes the mechanism from transduction.

Bacterial conjugation was discovered by Lederberg and Tatum (1946) when testing pairs of mutant strains of *E. coli* K12 for evidence for DNA transfer and recombination. From a mixture of a strain that required phenylalanine, cysteine, and biotin (a triple auxotroph), and

another that required threonine, leucine, and thiamine, they obtained some clones that were prototrophs, i.e. they required none of the nutrients required by the two parental strains, and other clones with various combinations of these requirements. These recombinant clones could only have arisen as the result of acquisition of chromosomal DNA from one bacterial cell by the other. Further studies, over several years, showed that the recombination was not the result of sexual reproduction in the normal sense of equal participation of both parents in zygote formation. Rather, it appeared that only a small amount of DNA from the 'male' (donor) parent was incorporated into the offspring (recombinants) which otherwise showed all the characteristics of the 'female' (recipient) parent. The capacity to donate genetic information (DNA) in these experiments was shown to depend upon possession of the F (fertility) factor. Strains were found that had become infertile, having lost their F factor, but they could regain fertility by contact with an F-carrying (F^+) strain (Hayes 1953a). At the time of these experiments, the role of DNA and the nature of the F factor were unknown; the F factor is now known to be a conjugative plasmid (see below).

In the first conjugation experiments the bacterial characters transferred were encoded by chromosomal genes. The F factor mediated transfer of part of the donor (F^+) cell's chromosome and this was rescued by homologous recombination into the chromosome of the recipient (F^-) cell, resulting in recombinant clones of bacteria with new assortments of characters. The recombinants remained F^-, i.e. they did not also acquire the F factor.

Conjugation is not an intrinsic function of bacteria but is determined by a variety of plasmids of which the F factor is just one. Conjugation normally functions to transfer plasmids from one bacterial cell to another. Conjugal transfer of chromosomal DNA is a relatively infrequent event, but many different plasmids are able to mobilize chromosomal genes with various degrees of efficiency. Chromosome-mobilizing ability (cma) is a byproduct that arises from certain interactions of the plasmids concerned with the bacterial chromosome, just as transduction of chromosomal genes is a byproduct of phage particle production.

For many years, conjugation was thought to be the prerogative of plasmids found in gram-negative cells, and most of our knowledge derives from these systems (Wilkins 1995). However, conjugation systems have been reported in gram-positive bacteria, notably strains of *E. faecalis*. The mechanics of these systems appear to differ somewhat from those found in gram-negative bacteria, primarily in the way donor and recipient cells are paired (Clewell et al. 1986; Grohmann et al. 2003).

Conjugation determined by F

F was the first conjugative plasmid to be discovered and the functions that mediate conjugation have been analyzed in detail. The genes that determine these functions are arranged as a continuous array, mostly in a single operon on the F factor in a region c. 30 kb in length, called the transfer (*tra*) region (Firth et al. 1996). This cluster, comprising approximately 24 genes, is found not only on the F factor but also on several resistance (R) plasmids, found in members of the Enterobacteriaceae, e.g. Rl and R100. Other plasmids encode unrelated but analogous Tra functions. Several different conjugation systems have now been described (Wilkins 1995; Zechner et al. 2000).

Conjugative pili

For conjugation to occur, donor and recipient cells must be in physical contact. Establishing contact is part random and part directed, in the sense that although encounters between donor and recipient cells happen by chance, the cells are joined by design. In gram-negative systems, the first link is made by thin protein filaments on the donor cell, called conjugative or 'sex' pili. These can be visualized by electron microscopy (Figure 9). Cells that lack conjugative pill cannot transfer DNA. Sex pili are essentially fiber polymers of a protein subunit called pilin. The current view is that a sex pilus effects the initial contact between the donor and recipient cells, via an interaction between a binding ligand at the tip of the pilus and its cognate receptor on the

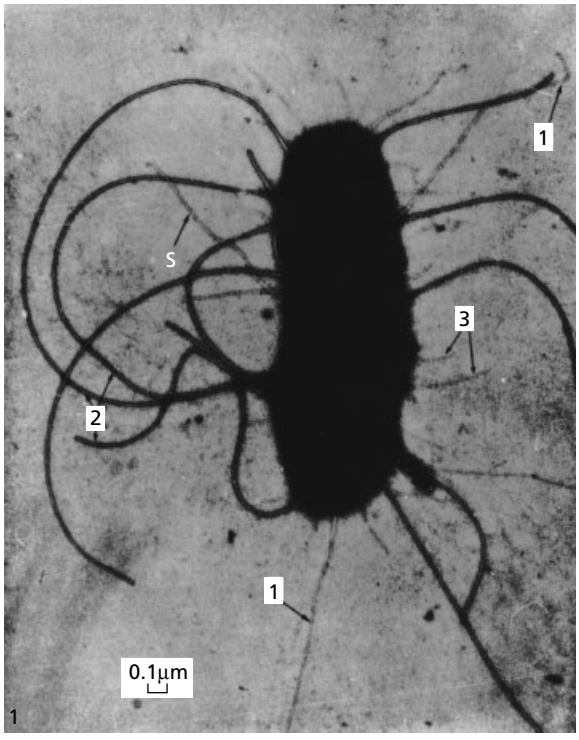

Figure 9 E. coli *K12 F .*The electron micrograph shows three kinds of appendage to the cell: 1, F pili; 2, flagella; and 3, common pili or fimbriae (from Meynell et al. 1968)

surface of the recipient cell. The pilus is then retracted into the donor, by depolymerization, in the process drawing the two cells together until direct contact is made. Pilin protein has been found as a pool of unpolymerized molecules in the outer membrane of the cell.

Conjugative pili may act as receptors for bacteriophages. F^+ cells are therefore susceptible to certain phages that cannot infect F^- bacteria whereas some other phages will infect only cells that carry one of another class of conjugative plasmid. Because these phages are specific for particular pili, they can be used as indicators for the presence of particular types of plasmids (Willetts 1988).

Mating pair formation

Random collision of bacteria is the first stage in conjugation or mating; plasmid transfer is rarely detected at low cell densities (Broda 1979). The initial link between donor and recipient cells, made by the sex pilus, is fragile and easily disrupted (e.g. by the shear force generated by pipetting), so not all donor–recipient encounters are productive. Before plasmid DNA is transferred, cell–cell attachment is strengthened, in the sense that much greater force than that generated by pipetting is needed to separate them. This state reflects the direct cell-to-cell attachment made after pilus retraction, and which is needed for formation of the DNA transfer channel between the participating cells. Such cell pairs can be forcibly split by vigorous treatment, e.g. by vortex mixing or in an electric blender. Once a stable mating pair is formed, initiation of F transfer is rapid and plasmid transfer takes about 2 min. When transfer has been completed, both cells contain F. Thereafter, the cells separate and both can initiate further rounds of F transfer.

High frequency of recombination (Hfr) and F′ formation

The first bacterial conjugation experiments involved transfer of chromosomal genes mediated by F. For this to occur, F must first fuse with the bacterial chromosome to form one large circular molecule. F, like many other plasmids, carries several transposable elements, specifically IS*2*, IS*3*, and γδ (Tn*1000*). Copies of the IS sequences are also found on the chromosome of *E. coli* and so can serve as loci for recombination between F and the chromosome (Brooks Low 1996; Deonier 1996). A single crossover between an IS element on F and a copy of the same element on the chromosome inserts one replicon into the other to form one large conjugative DNA molecule, transfer of which can proceed from the origin of transfer (*oriT*) of the integrated plasmid. Plasmid integration into the chromosome can also result from transposition (by, for example, γδ) with the formation of a transposition cointegrate. Either mechanism can generate integration events that may be transient or relatively stable. *E. coli* clones with the F factor stably integrated into the chromosome are called high frequency of recombination (Hfr) strains because, in matings in which these are donors, chromosomal genes are transferred to recipient cells at high frequency and large numbers of recombinants can be recovered (Hayes 1953b). Although initiation of transfer of DNA from *oriT* is rapid once a stable mating pair is formed, because the chromosome is about 50 times as long as F, complete transfer of the plasmid-chromosome cointegrate takes about 100 min (cf. approximately 2 min for F itself). In practice, mating pairs usually separate before this, so the chromosome is rarely transferred in its entirety.

F can be inserted into the bacterial chromosome at numerous loci and in either orientation. For each Hfr strain the chromosome is transferred to recipients unidirectionally from the *oriT* of the integrated F factor. Genes nearest the transferring end of F enter the recipient first (Figure 10). As a consequence, these donor alleles are recovered in greatest numbers in recombinants. The further a gene is from the leading end of F, the lower the probability that it will be transferred because, as noted above, it is rare that the entire chromosome is transferred; i.e. the longer a mating proceeds, the greater the probability that the participating cells will separate. One consequence is that chromosomal genes are transferred as a gradient from the point in the chromosome where F is inserted. Accordingly, these gradients can be plotted to show the positions of the genes in relation to the *oriT* of the integrated F. The same gradient, more directly related

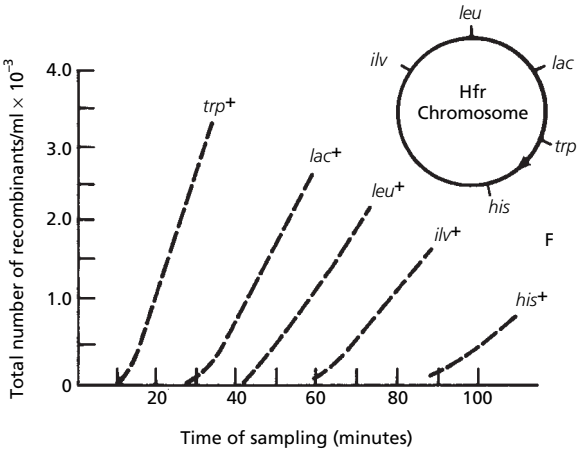

Figure 10 *Interrupted mating experiment. An Hfr strain of* E. coli, *with F inserted at the position shown, was mixed with an F⁻ strain that was* lac *(lactose nonfermenting),* trp, leu, ilv, his *(required tryptophan, leucine, isoleucine–valine and histidine for growth),* str *(streptomycin-resistant). Samples removed from the mixture at times shown were 'whirl-mixed' and plated on medium selective for the respective recombinants and containing streptomycin (to inhibit the Hfr donor).*

to the time of entry of each gene into recipient cells, can be determined from the results of interrupted matings. In these experiments, samples of a mating mixture are removed at intervals and diluted so as to prevent further mating pair formation. Mating pairs are separated by shearing in a blender or mixer and the cell suspension is then plated onto selective media to detect recombinants (Figure 10). When such experiments are performed with several different Hfr strains, the results indicate that the chromosome of *E. coli* is a circular molecule, because linear permutations of the same circular gene array are always obtained. As a consequence, the map of the *E. coli* chromosome is depicted as a circle with 100 min as reference points (Berlyn et al. 1996). Similar experiments with other bacteria, notably *S.* Typhimurium, *Proteus mirabilis*, *P. aeruginosa*, and *P. putida*, using F or a suitable analog, have shown that the chromosomes of these are also circular and similar in size (see O'Brien 1987).

When a plasmid integrates into the chromosome, either by transposition or by recombination between copies of a common sequence (e.g. an IS element), the overall result is the same, namely, formation of a cointegrate in which the plasmid is flanked by direct repeats of the transposable element or of the common sequence. Recombination across these direct repeats will restore the plasmid to its autonomous state. The integrated F of an Hfr strain can be excised from the chromosome in this way. Sometimes, however, excision is not precise and chromosomal DNA adjacent to one side or to both sides of the integrated plasmid is also removed and becomes part of the plasmid; sometimes a remnant of F is left in the chromosome. The derivative plasmids generated by the imprecise excision events are called plasmid primes; e.g. F′*lac* is F with the *lac* operon of *E. coli* incorporated into it. In this case the operon is functional so that when an F′*lac is* transferred to a lactose nonfermenting strain the transconjugants (i.e. the progeny of the cross) are *lac*$^+$ (i.e. are able to ferment lactose).

E. coli K12 strains that carry an F′ plasmid are normally diploid for the chromosomal sequence carried on the plasmid. Recombination between these homologous sequences may be frequent and results in re-entry of the F sequence into the chromosome to generate an Hfr strain with the same origin and direction of chromosome transfer as the Hfr from which the F′ originated. In practice, F′ cultures transfer chromosomal DNA at frequencies between that of a normal F$^+$ culture (with autonomous F) and that of the originating Hfr strain, because the cells in the culture are a mixture of those with the F′ integrated into the chromosome and others in which the plasmid is autonomous, i.e. the integrated and free plasmid forms in these cell lines are in dynamic equilibrium. This phenomenon is not, in principle, restricted to F. Any plasmid can be integrated into the bacterial chromosome by a suitable transposition with subsequent imprecise excision generating plasmid primes that, in turn, can be used in mapping studies, provided that the original plasmid mediates its own transfer.

F or F′ plasmids can be transferred to species other than *E. coli,* including ones belonging to different genera, such as *Yersinia* and *Vibrio* and the *E. coli* genes are expressed in these organisms. In the main, incorporation of chromosomal DNA from *E. coli* into the chromosomes of bacteria of other genera is not observed, unless there is a close phylogenetic relationship as, for example, between *E. coli* and *Shigella* spp., because there is insufficient homology to permit recombination. Even between *E. coli* and *Salmonella*, chromosomal recombination is rare. As might be expected, however, F can insert into the chromosomes of those bacteria in which it can be established, probably via the activities of the transposable elements it carries, to generate Hfr strains, so furnishing a tool for genetic analysis.

Conjugation in other genera

Conjugative plasmids have been identified in many different bacteria including all gram-negative enterobacteria, in species of *Pasteurella*, *Yersinia*, and many nonfermenting gram-negative aerobes such as *Pseudomonas* and *Acinetobacter*, as well as in *Haemophilus*, *Neisseria*, *Campylobacter*, and *Bacteroides* spp., and gram-positive organisms such as *Streptomyces*, *Streptococcus*, and *Clostridium.* Demonstration of conjugation in all these species does not necessarily imply that the mechanisms are the same; for example, conjugative pili have not been identified in all the genera listed above. However, conjugative plasmids in *Pseudomonas* (Holloway et al. 1979), *Streptomyces* (Hopwood et al. 1973), and *Acinetobacter* (Towner and Vivian 1976) spp. mediate chromosomal DNA transfer in ways that appear to be analogous to that of F in *E. coli.*

In some genera, conjugation and transfer of antibiotic resistance determinants have been observed although no plasmid DNA could be detected, before or after transfer (Stuy 1980). In these systems the mobile DNA is normally part of the bacterial chromosome, but the strains do not behave as Hfr strains. Rather, transfer involves a discrete DNA sequence. During transfer the element behaves like a plasmid, i.e. it separates from the chromosome of the donor cell, but it cannot be isolated by conventional plasmid isolation procedures. These transfer systems are now known to reflect the activity of conjugative transposons and other ICEs (see above). One example is typified by the transposon Tn*916* which was first identified in the chromosome of a strain of *E. faecalis*. Tn*916* encodes resistance to tetracycline and accommodates conjugation functions that mediate transfer of the transposon alone, even between Rec$^-$ hosts (Franke and Clewell 1981; Clewell et al. 1988). No plasmid is involved and the element transposes from the

chromosome in the donor cell into the chromosome in the recipient (Salyers et al. 1995).

The conjugative functions of F are naturally derepressed, so that F transfers at high frequency. By contrast, most natural plasmids transfer at rather low frequencies. In some cases, mutant plasmids can be isolated that transfer at greatly increased frequencies, indicating that expression of the *tra* genes on these plasmids is normally genetically repressed. In other cases, genetic derepression has not been found, although the transfer frequency is relatively low; an example is the R plasmid RP4, which originated in a strain of *P. aeruginosa* but which can be transferred to virtually all gram-negative bacteria (Thomas and Smith 1987).

One consequence of regulating the expression of a set of transfer genes negatively, i.e. with a repressor, is that immediately after plasmid transfer expression of the transfer system is transiently derepressed in the recipient and remains so until sufficient repressor has been synthesized to re-establish control. During this time the recipient temporarily becomes capable of high-frequency plasmid transfer. If there are sufficient potential recipient cells available, the plasmid will spread rapidly from one cell to another in a chain reaction (epidemic spread) until the system is saturated, as was seen in early studies on the transfer kinetics of R plasmids such as Rl and R100. This finding has practical significance in the design of experiments to test for plasmid transfer (Broda 1979; Willetts 1988).

Conjugative plasmids in genera other than those of the Enterobacteriaceae may also repress expression of their transfer genes. In *E. coli* the only mechanism known to lift repression, other than mutation, is transfer to a new host. In other genera, however, induction of the conjugation functions has been reported, e.g. conjugation mediated by a tetracycline resistance plasmid in *Bacteroides fragilis* is induced by low concentrations of tetracycline together with induction of resistance to tetracycline (Privitera et al. 1981). This phenomenon does not appear to be widespread.

Conjugation in gram-positive bacteria appears to differ somewhat from that in gram-negative bacteria in the manner in which the donor and recipient cells are brought together. In *E. faecalis*, conjugation is mediated via sex pheromones excreted by potential recipient cells (Clewell 1993). These peptides cause donor and recipient cells to clump to form mating aggregates, a necessary prerequisite to plasmid transfer. Upon acquisition of the plasmid, the recipient promptly ceases to produce the particular pheromone that triggered plasmid transfer. Different plasmids respond to different pheromones and potential recipient cells produce several.

An unusual form of plasmid transfer, called phage-mediated conjugation, has been reported to occur with some strains of *S. aureus*. Lacey (1980) described the carriage of penicillin and cadmium resistance genes by elements with some of the characters of defective phages. Not only were these genetic elements themselves transmissible between non-lysogenic staphylococci, but they could also mediate transfer of unlinked resistance plasmids in mixed culture (but not in conventional transduction experiments).

Transduction

Gene transfer between bacteria can be mediated by some bacteriophages in a process known as transduction. Transduction is the transmission of a piece of host DNA from one cell (the donor) to another (the recipient) by a phage particle. Two forms have been described: generalized transduction (Masters 1996) and specialized transduction (Weisberg 1996). In the first, any part of the donor genome can be transferred to a suitable recipient; in the second, specific sequences are transferred.

Generalized transduction

Phage P1 replicates during infection of its *E. coli* host cell to generate long concatemers (head-to-tail multimers) of DNA that are subsequently cut into new phage chromosomes by the assembling phage particles. Transducing particles of P1 contain a length of the host chromosome, equivalent in size to the phage genome, in place of the phage DNA, indicating that some heads erroneously take in a section of bacterial rather than phage DNA during phage particle development. Such particles are morphologically normal and are released in the lysate along with ordinary phage particles; they can then infect fresh cells, injecting the contents of the head into the cell in the usual manner. Although the length of bacterial DNA transduced is similar to that of a normal phage chromosome, there is conflicting evidence as to whether particular regions of the host chromosome are preferentially transferred. Such transducing particles comprise approximately 1 in 100 000 of the phage particles in a phage lysate. A phage-infected cell has a roughly similar amount of phage DNA at the end of the replication period as there was bacterial DNA at the outset, yet only a small minority of phage particles contain bacterial DNA, indicating that the head-filling process preferentially packages phage rather than host DNA. Transduced genes are recovered by homologous recombination between the transferred DNA and the recipient cell's chromosome, although it is not uncommon for the transduced DNA to persist extrachromosomally but unreplicated in the cell. In this case it is inherited by only one daughter cell at cell division, a phenomenon called abortive transduction. The frequency of transduction of any one bacterial genetic marker is around 10^{-6} per surviving recipient cell.

Insofar as generalized (and specialized) transduction depends on infection by a phage, it is usual to find that bacterial genes can be transduced only to a recipient of

the same species, or perhaps even strain, as the donor; the host range of a phage is generally delimited by the presence of specific receptors on the surface of the cell. Although best studied with phages P1 and P22, two temperate phages, generalized transduction is not a property of temperate phages alone. The lysates of even highly virulent phages, such as those in the T series in *E. coli*, are found to include some particles containing host DNA (Borchert and Drexler 1980; Young and Edlin 1983), but if such particles infect a recipient and establish a transductant, the latter is usually killed by superinfection with other lytic particles. In these cases, transduction is only seen at low multiplicities of infection, i.e. when bacteria outnumber bacteriophage.

Generalized transducing phages can also transduce plasmids, as well as fragments of the donor chromosome, provided these are sufficiently small to be contained within the phage head; where plasmids are too large to be accommodated in the phage head, variants with partial deletions may be transduced, a useful technique for the isolation of plasmid deletion mutants (transductional shortening) before the advent of genetic engineering. The transduction of antibiotic resistance plasmids in staphylococci is of considerable clinical significance (Lacey 1973, 1984). Unexpectedly, the frequency of cotransduction of two plasmids in *S. aureus* is often much higher than would be predicted from the transduction frequencies of each plasmid separately, a result that may reflect cointegrate formation between the two plasmids (Novick et al. 1981, 1986).

Specialized transduction

Phage λ lysogenizes *E. coli* when the phage genome integrates into the *E. coli* chromosome at a specific site by means of a recombination event mediated by the phage function Int and host function IHF (Arber 1983). On induction of the lytic cycle, the integration event is reversed and the phage genome is excised in the presence of an additional phage function, Xis. Both integration and excision are highly specific with respect to the sites in the DNA at which recombination occurs. Occasionally, however, recombination during the excision process occurs between two sites other than the normal attachment regions of phage and host DNA, usually one within the prophage and one just outside (see Figure 11). The consequence is that a ring of DNA is excised that consists primarily of λ genes plus a few host genes from one side of the attachment region. In the presence of other λ DNA molecules undergoing normal lytic replication in the cell, this hybrid DNA can be packaged in a λ head and released in the phage lysate where it is available to infect a further cell and inject into it DNA that contains some host genes.

The gene clusters on the bacterial chromosome that lie closest to the λ integration site and are the most

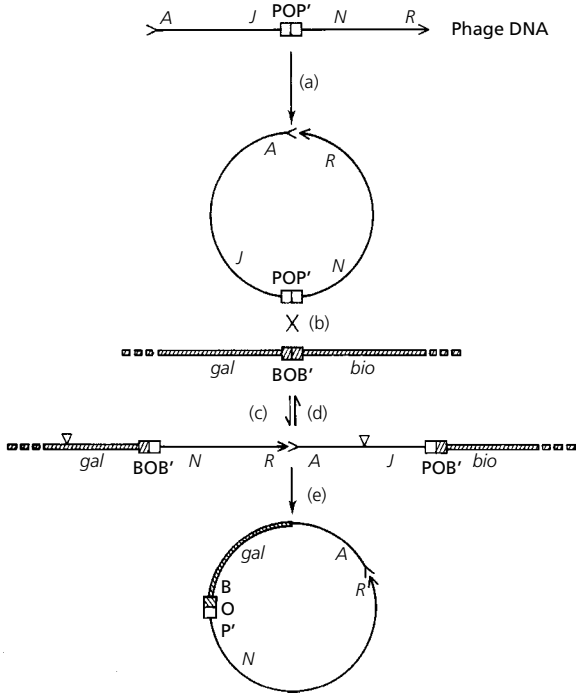

Figure 11 *The Campbell model for prophage λ integration into the bacterial chromosome.* **(a)** *Circularization of λ DNA by attachment of cohesive ends (arrows) followed by ligation.* **(b)** *and* **(c)** *Integration by site-specific recombination between phage (POP′) and host (BOB′) attachment regions; four phage genes (*A, J, N, R*) and two host gene clusters (*gal, bio*) are shown for reference, and phage integrase (*int^+ *product) and integration host factor (IHF) are required. Note that the prophage genes are permuted relative to those in the phage DNA.* **(d)** *Normal excision: integrase and excisase (*xis^+ *product) are required.* **(e)** *Abnormal excision, by recombination between two points (∇) other than the attachment regions, generating a defective λ particle carrying host* gal *genes a particle carrying* bio *genes can be formed similarly.*

easily selected in genetic crosses, i.e. *gal* and *bio* (Figure 11), and hence it is these genes that are readily found in specialized transducing particles represented as λ*gal* and λ*bio*. Lambdoid phages (Campbell 1994) are closely related to λ, but many have a different host integration site and are therefore able to transduce different genes; thus, ϕ80 acts as a specialized transducing phage for the tryptophan genes in *E. coli*. Less closely related phages are exemplified by P22 in *S.* Typhimurium, the prophage of which is integrated within the proline gene cluster; hence P22, which is a generalized transducing phage in *Salmonella*, is a specialized transducing phage for the *pro* region.

There are two constraints on the ability of a chromosomally integrated λ phage to form a specialized transducing particle: the recombination event must not exclude the cohesive end (*cos* site) of the phage genome and the total length of DNA in the particle must not significantly exceed that of wild-type λ itself, i.e. 5 percent increase or less, to allow for packaging in the head. A consequence of the second point is that, if the

phage acquires some host genes, it will normally have to lose some phage DNA to accommodate the acquisition; hence such phage derivatives are often defective in their abilities to propagate themselves and so require a helper phage to supply the missing function(s). With the exception of the limitation on genome size, specialized transducing phage formation is closely similar to the process by which hybrid plasmids such as F-primes are formed (Hu et al. 1975).

Specialized transduction differs from generalized transduction in many respects. Two are significant. The transducible genes are limited to those near the prophage integration site and the transducing particle contains a hybrid of phage and bacterial DNA, rather than consisting entirely of the latter. As a consequence, the transduced genes can be added to the genome of the recipient cell rather than replacing recipient genes, as in generalized transduction of chromosomal markers, because the modified phage genome can integrate into the prophage attachment site of the recipient's DNA. When such transductants are induced to enter a lytic cycle, the integrated hybrid DNA is excised and replicated to generate a large number of copies (a process which may require the presence of superinfecting normal particles to supply missing phage functions), each of which carries bacterial genes; these copies are packaged to form phage particles and if this lysate is then allowed to infect a further population of sensitive cells, the transduction frequency of the phage-associated genes increases about 1 000-fold, giving rise to high-frequency transduction (HFT).

Protoplast fusion

When the cell wall of a bacterial cell is removed, an osmotically fragile form called a protoplast is generated. This remains intact as long as the growth medium is osmotically buffered. Bacterial protoplasts can fuse with one another, a process called protoplast fusion. This generates cytoplasmic bridges that allow mixing of the cytoplasms of the fused cells and exchange of genetic material. Fusions can be obtained between unrelated cells, even between members of different kingdoms, and gene transfer by this mechanism has been termed genetic transfusion.

As in the other forms of gene transfer, plasmid or phage DNA can be transferred interspecifically or intergenerically, but, for recombination between chromosomal DNAs to occur, a close relationship between the participating cells is necessary in practice. In the case of protoplast fusions, two complete chromosomes are brought together to generate an artificial diploid and from such fusions haploid recombinants with many permutations of the traits of the parent cells can be recovered. Protoplast fusion is an artificial system of gene transfer that has little or no demonstrated relevance to gene transfer in nature. However, protoplast (or spheroplast) fusion has proved to be a valuable experimental tool that is likely to continue to prove useful in the advance of molecular genetics (Gokhale et al. 1993).

PLASMIDS

Plasmids are extrachromosomal, autonomous DNA molecules (i.e. replicons) found in many bacterial species (Stanisich 1988; Thomas 2000). Plasmids have also been found in lower eukaryotes, e.g. the 2 μm plasmid of yeast. The term 'plasmid' was proposed by Lederberg (1952) for all extrachromosomal genetic structures that can replicate autonomously. Here, the adjective 'autonomous' means self-governing and separate from the chromosome of the host, rather than an entity capable of separate existence, in that plasmids are obligate endosymbionts of bacteria, using the replication enzymes of their host to ensure their own propagation, but retaining control over replication. They differ from bacteriophages in having no independent, extracellular form. Most plasmids, whether from gram-negative or gram-positive bacteria, are circular elements, but linear plasmids have been reported in *Streptomyces* spp. and in *Rhodococcus* spp. (Hinnebusch and Tilly 1993). As more bacterial genomes have been sequenced, it has become clear that a number of species have multiple chromosomes rather than one (Cole and Saint-Girons 1999), some of which have sizes similar to a large plasmid. This raises the interesting question as to when such molecules should be considered as plasmids and when as minichromosomes. To date, a definition is lacking.

The term 'episome' has, in the past, been used as a synonym for plasmid. Episomes were defined as genetic elements that could exist and be replicated in either of two modes; autonomously or as part of a cointegrated structure with the bacterial chromosome. As it came to be realized that almost any plasmid can be integrated into the bacterial chromosome, the term lost its usefulness as the definition of a particular class of replicon (Novick et al. 1976). However, the adjective 'episomal' may be useful when applied in particular circumstances, e.g. to describe the state of F in an Hfr strain.

Plasmids are widespread (Stanisich 1988), but the practical importance of bacterial plasmids was first recognized in the early 1960s when transferable drug resistance was discovered (Watanabe 1963). Although plasmids represent only a fraction of the prokaryotic gene pool, they have attracted, and continue to attract, much research interest because the genes they carry determine many of the more interesting features displayed by bacteria, e.g. resistance to antibiotics and heavy metals, virulence, symbiosis and nitrogen fixation, exotic metabolic capacity, and many more (Stanisich 1988). They also serve as convenient models, particularly of replication and partition mechanisms (see Thomas 2000).

The extrachromosomal natures of F and of the first R plasmids discovered were deduced from their genetic behaviors. One feature is the tendency for clones in the culture to lose the plasmid, the set of plasmid-determined characters thus being lost simultaneously and irreversibly. The stability of inheritance of plasmids varies from one to another; some are lost very easily, at rates much higher than the rate of mutation, e.g. 1 percent or more of cell progeny may not inherit the plasmid in any one generation, compared with normal mutation frequencies in the range 1 in 10^6–10^8 per generation. Others are very stable indeed and are rarely, if ever, lost. Some plasmids can be eliminated from the host artificially (cured) by treatment with one of a variety of chemicals (curing agents) (Stanisich 1988). The quinolone drugs seem to be particularly effective (Weisser and Wiedemann 1985). However, no single curing agent or treatment can be relied upon; finding an appropriate agent or treatment to cure a specific plasmid is an empirical exercise that may well fail (Caro et al. 1984). The F plasmid is readily eliminated by treatment with acridine orange (Hirota 1960), but few others succumb to this agent. Some plasmids have temperature-sensitive replication systems and so are eliminated by growth of the cell at the nonpermissive temperature (May et al. 1964; Yokota et al. 1969), but this feature is not widespread. It has also been reported that the conversion of some bacteria to protoplasts (spheroplasts), e.g. *B. subtilis* and *S. aureus*, can result in plasmid loss. Again this is not a universal finding. Irreversible loss of a particular character, or set of characters, either spontaneously or after treatment, is still powerful genetic evidence for the existence of a plasmid but the inability to cure a specific feature, for the reasons given above, does not necessarily rule out plasmid involvement.

With the development of methods for isolating plasmid DNA, the presence of a plasmid can be determined directly. Modern small-scale preparative procedures (Sambrook et al. 1989) and the use of agarose gel electrophoresis allow plasmids to be detected in very small culture volumes (0.5–1.0 ml of a stationary phase culture). Plasmid DNA can be purified and reintroduced into bacterial cells by transformation (or electroporation) to establish definitively the connection between a phenotype of interest and the plasmid. However, this is still not always possible, particularly with large plasmids ($\geqslant$100 kb), or when investigating a poorly characterized bacterium, in which case it may be necessary to fall back on classical genetic techniques (conjugation, transduction, curing).

Plasmid genes

The only genes that are formally necessary to a plasmid are those needed for its replication. The amount of DNA devoted to this task is surprisingly small (Scott 1984; Thomas and Smith 1987) and rarely, if ever, exceeds a few kilobases. The minimum requirement is an origin sequence, origin of vegetative replication (*oriV*), at which replication can start, all enzyme functions being provided by the host. Several small plasmids have this arrangement, e.g. ColEI from *E. coli* and the related plasmid, CloDF13 from *Enterobacter cloacae*. In addition to an *oriV*, such plasmids also encode functions that control the extent of plasmid replication, i.e. ensure that the plasmid copy number per cell is maintained within fairly narrow limits specific to the particular plasmid (Sherratt 1986). In these plasmids no more than 1–2 kb is devoted to plasmid replication and its control. In others, more complex arrangements have evolved both to execute replication and to regulate it (Espinosa et al. 2000).

There are basically two modes of replication for circular plasmids: θ (theta) replication and RC (rolling circle) replication (Helinski et al. 1996). In the former, replication proceeds from a fixed origin in a unidirectional or bidirectional manner round the plasmid circle and both strands of the plasmid are replicated simultaneously, in a manner precisely equivalent to *E. coli* chromosome replication. Both strands of the parent plasmid remain intact during the replication process. The type of replication gets its name from the fact that a part replicated plasmid/chromosome resembles the Greek letter theta, θ, if opened out. For most of the plasmids in gram-negative organisms studied, this is the mode of replication utilized.

A few plasmids from gram-negative bacteria and the single-stranded coliphages (Baas and Jansz 1988) have been shown to use the alternative, RC replication mode, as does a family of highly related plasmids in gram-positive bacteria (del Solar et al. 1993). These plasmids always encode an initiator protein which introduces a site-specific nick at the double-strand origin (DSO) to generate a 3′-OH group, which serves as a priming terminus. In some cases, it has been shown that the initiator is covalently attached to the 5′-phosphate exposed by the cut. Replication proceeds by extension from the 3′-OH primer site, using the complementary strand (designated the plus-strand) as template. The old complementary strand (called the minus-strand) is displaced as replication proceeds. Once replication has traveled right round the circle (hence the designation RC) the minus-strand is circularized. Consequently, one double-stranded DNA molecule and one single-stranded molecule result. The circular single-stranded minus-strand is then converted to a double-stranded molecule using a second origin of replication that is specific to the minus-strand. Replication of plasmids, including linear plasmids, has been reviewed by Helinski et al. (1996) and by Espinosa et al. (2000).

Plasmids range in size from c. 1 kb to >400 kb (equivalent to c. 10 percent of the *E. coli* chromosome).

The smallest have only enough DNA to accommodate two or three small genes (e.g. Pl5A; Chang and Cohen 1978). Nevertheless, small plasmids are relatively abundant (Figure 12), though many confer no obvious phenotype on their host. Such plasmids (large or small) are said to be cryptic, a description that is largely an acknowledgment of ignorance of function.

Plasmids capable of mediating conjugation have a minimum size of c. 30 kb. Several have now been analyzed extensively with respect to the plasmid-encoded information needed for replication. Here, again, it is found that relatively little genetic content is devoted to replication. In addition to *oriV*, these plasmids encode one or two specific proteins necessary for their own replication, together with one or more replication-control functions (Scott 1984; Thomas and Smith 1987; see also Thomas 2000). These functions define the essential replicon of the plasmid and can be encoded in 4–5 kb (see Thomas 2000).

The relatively small amount of plasmid-encoded information needed for plasmid replication is a reflection of the fact that most of the replication apparatus is provided by the host. Most of the panoply of functions used to replicate the bacterial chromosome is borrowed to replicate the plasmid. Although not all plasmids have exactly the same requirements, they all use a common core of enzymes, e.g. either all or the bulk of the DNA synthesis is carried out by the main DNA polymerase of the cell, e.g. in *E. coli* DNA polymerase III is used. In *E. coli*, a number of small plasmids (e.g. ColE1 and related plasmids) require DNA polymerase I (product of the *polA* gene) in the early stages of replication, before switching to DNA polymerase III for the bulk of the synthesis. Consequently, such plasmids cannot be established in a *polA* mutant strain of *E. coli.* Most plasmids described to date, however, do not show this requirement.

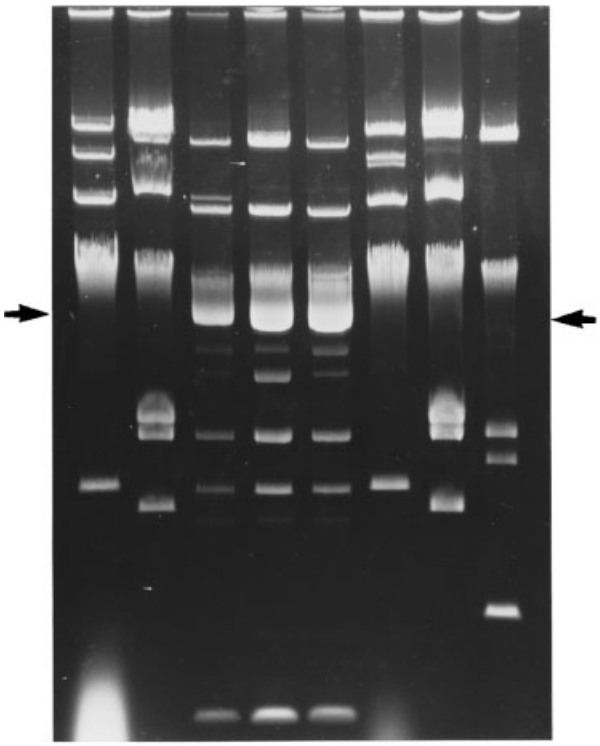

Figure 12 *Plasmid profiles from isolates of* E. coli *obtained from slurry waste from a calf-rearing unit. The diffuse band (arrows) in each track represents DNA fragments (chromosome and plasmid) that arose during the course of the preparation. Plasmid size decreases from top to bottom. The smallest plasmids seen in these preparations have sizes of 1–2 kb.*

F and many other plasmids maintain themselves at a low copy number, i.e. one to four copies of the plasmid per bacterial chromosome. These plasmids have been described as being under stringent replication control. By contrast, other plasmids, usually small ones such as ColEI, maintain themselves at a relatively high plasmid–chromosome ratio (15–20). Plasmids of this type are said to be subject to relaxed replication control because it was initially thought that replication control of these latter elements was less rigorous than for low copy number plasmids. This is now known not to be true; rather, the threshold value at which inhibition of replication operates is set higher. Once activated it is just as efficient.

For each plasmid there is a characteristic copy number, although this can be altered by mutation. Some plasmids also show changes in copy number in response to the prevailing culture conditions; for example, some plasmids continue to replicate when the cells enter stationary phase (when chromosomal replication stops) with the accumulation of large numbers of plasmid molecules per cell. Treatment of a culture of *E. coli* carrying ColE1, or a related plasmid, with chloramphenicol (at a concentration sufficient to inhibit protein synthesis) has the same effect; whereas the initiation of new rounds of replication of the bacterial chromosome (and many plasmids) requires de novo protein synthesis, that of ColE1 does not (see Thomas 2000).

The genes that control plasmid replication include functions that act repressively, i.e. inhibit replication. One consequence is plasmid incompatibility. It was discovered early that two variants of the same plasmid cannot be maintained stably in the same bacterial cell, i.e. they are incompatible. This arises because each directs the production of replication inhibitors that act on the other replicon, as well as on themselves. The consequence is that the content of plasmid molecules in the cell is set to a lower level than the sum of the two individual copy numbers. If the plasmids involved are unit, or low copy number plasmids, plasmid segregation at cell division is a likely result, i.e. clones emerge in which one or other of the plasmids has not been inherited (Novick 1987). Plasmids with unrelated replication control systems do not, in general, interact in this way and so do not destabilize each other; they are said to be compatible. Plasmids that are incompatible are said to belong to the same incompatibility (Inc) group; plasmids that are compatible necessarily belong to different incompatibility groups.

Plasmid partition systems

To be inherited stably, plasmid DNA not only has to be replicated but at each cell division both progeny cells must obtain at least one copy of the plasmid (which will be replicated until the appropriate copy number has been achieved). For low copy number plasmids such as F and some common R plasmids (Rl, R100), plasmid distribution at cell division – namely, plasmid partition – is an active process involving both plasmid- and host-specified products (Hiraga 1992; Draper and Gober 2002).

The former are designated *par* functions. The components comprise a small sequence of a few hundred base pairs, carried on the plasmid, that is believed to function like a primitive centromere to pair plasmids prior to cell division and one or more proteins that interact with it. These may be plasmid- or host chromosome-encoded. The system may direct plasmid DNA membrane association at or near the point of septum formation. If two different plasmids have related partition systems, to the extent that each is unable to distinguish the two plasmids, incompatibility will result. This will reinforce any incompatibility between the two plasmids that arises as a consequence of 'common' replication systems. However, the replication and partition functions on a plasmid act independently, as can be demonstrated by creating synthetic replicons with the replication system of one plasmid and the partition system of an unrelated plasmid. These hybrids are stably maintained, i.e. they are efficiently replicated and partitioned (Austin and Abeles 1983).

In contrast to the active partition described above, small plasmids with high copy number do not encode specific *par* functions. They rely on the random distribution of units to daughter cells. When the copy number is 15–20, the plasmid content of a cell immediately before cell division will be at least 30–40. Assuming random distribution of plasmids throughout the cell, the probability of one daughter cell inheriting the entire complement of plasmid molecules while the other inherits none is negligible (this would not be true for low copy number plasmids). Nevertheless, and somewhat paradoxically, some small, very high copy number cloning vectors generated in the laboratory are not efficiently inherited, in contrast to the plasmid from which they were derived.

If low copy number plasmids, in particular, are to be partitioned accurately, it is desirable, if not essential in all cases, that the molecules be present in the cell as monomers. Cells in a natural environment are recombination proficient. Hence they will actively pair and recombine homologous sequences, including plasmid DNA. A single crossover between two plasmid molecules will fuse them to form a dimer. If this were to happen with a unit copy number plasmid immediately after it had replicated and no steps were taken to reverse the event, at cell division one daughter cell would inherit both copies of the plasmid. The accumulation of plasmid dimers (and higher multimers) is prevented by plasmid-encoded, site-specific recombination systems (Austin et al. 1981; Lane et al. 1986; Dodd and Bennett 1987; Garnier et al. 1987; Krause and Guiney 1991; Eberl et al. 1994; Guhathakurta et al. 1996). These are specialized recombination systems that comprise a specific DNA sequence and a recombination enzyme that acts at the sequence (Smith 1988). The site must be part of the plasmid, but the enzyme can be either a plasmid-encoded function or a host function (Sherratt 1986; Dodd and Bennett 1987). These recombination systems rapidly convert plasmid multimers to their momomeric units, so reducing the chance of plasmid loss at cell division.

Post-segregational killing

Some plasmids have a third type of mechanism that acts to maintain their stability. These systems act after segregational loss of the plasmid to kill the plasmidless cell (Jensen and Gerdes 1995; Yarmolinsky 1995; Gerdes et al. 1997, 2000; Rawlings 1999). Each comprises two genes; one encodes a toxin, the other an antidote. The toxin is more stable than the antidote, which means that to neutralize the toxin the antidote must be produced continuously. This is possible as long as the cell carries a copy of the plasmid. However, in those unfortunate progeny that fail to acquire a copy of the plasmid at cell division, the toxin activity is duly unmasked as the antidote decays and the cell is killed.

A variation on the theme is encoded by the resistance plasmid R1. In this instance, the control exerted over the toxin is at the point of production, rather than inhibition of activity. The control locus, *sok*, overlaps the toxin gene, *hok*, which is encoded on the opposite strand of the DNA duplex. Both sequences are transcribed, but translation of the *hok* mRNA is prevented as a consequence of the two RNA transcripts annealing to one another over the region of overlap, where they are complementary. This prevents ribosome binding to the Hok mRNA. However, the *sok* RNA decays faster than the *hok* mRNA, so if the R1 plasmid is lost then the *hok* mRNA is translated. The toxin produced causes the collapse of the transmembrane potential and the cell dies (Gerdes et al. 1986, 1988).

Plasmid replication functions together with stability functions (*par* and site-specific recombination functions) comprise the minimum requirements of a stable, low copy number replicon, i.e. one that will be inherited efficiently despite there being very few copies of the plasmid. Partition and post-segregational killing mechanisms act in concert to provide stability (Brendler et al. 2004). The whole can be accommodated in a sequence of <10 kb (a stable miniplasmid derived from F, which is 94 kb in size, carries just 9.2 kb of F, in addition to a selectable marker).

Genes determining conjugation

Conjugation determined by F and by many other plasmids is a complex process requiring many genes. Accordingly, conjugative plasmids cannot be very small. The smallest conjugative plasmids in the Enterobacteriaceae are about 30 kb (of which 15–20 kb are devoted to transfer compared with F which devotes approximately 30 kb to transfer functions) (Avila and de la Cruz 1988; Thomas 1989; Zechner et al. 2000). Conjugation can be viewed as a two step process involving synthesis and transfer of DNA, the latter process mediated by a type IV secretion system (Llosa et al. 2002).

Most natural plasmids that are unable to mediate their own transfer can, nevertheless, be transferred conjugally by co-opting the transfer functions of a conjugative plasmid. Such plasmids, e.g. ColEI, have their own *oriT* and encode functions specific to it (mob genes). To transfer by conjugation, these plasmids require a helper plasmid to provide the missing transfer functions; for example, F can serve as a helper plasmid for ColE1 (Dougan and Sherratt 1977). Such plasmids are said to be mobilizable and mainly lack the ability to direct attachment of donor and recipient cells. A few plasmids possess only an origin of transfer, and transfer only when the other necessary transfer functions are provided by helper plasmids; for example, the small plasmid Pl5A, the progenitor of the cloning vector pACYC184 and its derivatives, has its own *oriT*, but to transfer it requires both Mob and Tra functions provided by ColEI and F (or equivalents), respectively.

Other plasmid genes

Replication and its control, maintenance, and transfer functions may be considered as inherent plasmid characteristics. Together, they direct both vertical (inheritance) and horizontal (transfer) transmission in bacterial populations. However, these features alone, no matter how intrinsically interesting, would have been insufficient to attract the degree of interest that bacterial plasmids have engendered. Indeed, until the discovery of transmissible multiple drug resistance (Watanabe 1963), the study of plasmids and their activities was a minority interest. The veritable explosion of interest shown since then reflects the variety of other genes, expression of which can affect the human condition, carried on plasmids.

Antibiotic resistance determined by plasmids was first discovered in Japan in the late 1950s. Until then it had been assumed that antibiotic resistance in bacteria, which had already become a clinical issue, resulted from the selection of chromosomal mutants, multiple resistance resulting from the sequential accumulation of mutations. Then, unexpectedly, epidemiological analysis of drug resistance in *Shigella flexneri* indicated that resistance could be transmitted between bacteria. Bacillary dysentery was common in Japan after the Second World War. By the mid-1950s, most Japanese infections with *S. flexneri* involved bacteria that were resistant to sulfonamides, so antibiotic treatment (now considered inappropriate) was switched to streptomycin, tetracycline, or chloramphenicol (much of it self-prescribed). In due course, a few strains resistant to the four unrelated drugs were isolated; thereafter such strains became progressively more common (Table 2). Isolates resistant to two drugs, which one would expect to see if sulfonamide-resistant clones mutated to resistance to another drug, were rarely isolated. Instead, in outbreaks of infection with a single *S. flexneri* serotype, strains from some patients had the multiple-resistance pattern, whereas others did not. Furthermore, *E. coli* strains with the same pattern of resistance were found in the feces of patients with dysentery. Given these observations, Akiba and, independently, Ochiai in 1959 (cited by Watanabe 1963) tested the hypothesis that multiple antibiotic resistance might be determined by an infective agent analogous to the F factor of *E. coli*. Mixed culture experiments proved this idea correct: multiple drug resistance was transferred from *S. flexneri* to *E. coli.* The infective agents are now called resistance (R) plasmids.

The increasing frequency of drug resistance in *S. flexneri* in Japan was not an isolated phenomenon. The emergence of resistance to antibiotics was recorded in diverse strains of bacteria worldwide: in *Shigella sonnei* in the London area, in *Salmonella* strains in the Netherlands, and in *S.* Typhimurium in England (see Datta and Nugent 1983). These cases differed to some extent from the Japanese experience in that there was a stepwise accumulation of resistance, first to sulfonamides and streptomycin, then to tetracycline, and subsequently (and infrequently) to chloramphenicol (Anderson 1968). Nevertheless, the resistance was primarily plasmid mediated and transmissible; ampicillin resistance then emerged, and within a decade had become common in *Salmonella* and *Shigella* strains throughout Europe (although it remained uncommon in Japan).

Table 2 *Multiple drug resistance in* Shigella flexneri *isolated in Japan*

Year	No. of isolates tested	Percentage multiresistant
1956	4399	0.02
1958	6563	2.9
1960	497	15
1962	6853	23
1964	5388	45
1966	4292	75
1968	1237	64
1970	562	74
1972	824	76

Multiresistant strains were resistant to chloramphenicol, tetracycline, streptomycin, and sulfonamide. Figures from Mitsuhashi (1977).

At the time of the discovery of R plasmids in the Enterobacteriaceae, multiresistant strains of *S. aureus* were a cause of concern in hospital infection. Penicillinase-producing strains of *S. aureus*, first recognized in the 1940s, had become common and had acquired resistance to new antibiotics as each was introduced into clinical practice. In 1963, it was shown that penicillinase synthesis by *S. aureus* was a plasmid-determined characteristic (Novick 1963), as are many other antibiotic resistances in that species (Lacey 1975). Penicillin-resistance plasmids in *S. aureus* have been studied extensively. They encode not only the penicillinase, but also the means to regulate its production which is induced when the cells are exposed to penicillin and other β-lactam agents. The mechanism involves a form of signal transduction, because the inducers (β-lactams) do not penetrate the cytoplasmic membrane (Everett et al. 1990; Bennett and Chopra 1993; Zhang et al. 2001). These plasmids often also encode resistance to mercury or cadmium salts, or both, and sometimes to erythromycin or fusidic acid. Resistance to tetracycline, chloramphenicol, and neomycin is also extrachromosomal in *S. aureus*, but these markers are usually found on separate plasmids.

Not only are many resistance determinants in *S. aureus* encoded by plasmids, but several are also carried on transposons (Murphy 1989). Tn*551*, encoding resistance to erythromycin, was the first to be discovered in *S. aureus* (Novick et al. 1979). Later, a transposon encoding resistance to gentamicin, kanamycin, tobramycin, trimethoprim, ethidium bromide, and quaternary ammonium compounds, designated Tn*4001*, was discovered (Lyon et al. 1984). This element was found in a multiresistant methicillin-resistant *S. aureus* (MRSA) (see Chapter 32, *Staphylococcus*) strain isolated in Melbourne. Strains of this type have caused concern worldwide because they are resistant to all β-lactam agents and many other antibiotics that might be used against them. While many antibiotic resistance genes in *S. aureus* are found on plasmids and transposons, the methicillin-resistance gene, *mecA*, is found on acquired sequences of 21–67 kb (Hiramatsu et al. 2001; Ma et al. 2002), termed SCC*mec* (staphylococcal cassette chromosome *mec*) elements (Katayama et al. 2000), which are integrated into the chromosome of *S. aureus* at a unique site, *attBscc,* found in an open reading frame of unknown function near the origin of replication (Hiramatsu et al. 2001). Integration is mediated by a site-specific recombination mechanism comprising two SCC*mec* genes, *ccrA* and *ccrB*, closely linked to *mecA*. A possible precursor of SCC*mec* elements, SCC_{12263}, that lacks *mecA* has been identified in the methicillin-susceptible strain *Staphylococcus hominis* GIFU12263 (Katayama et al. 2003).

The *mecA* gene encodes a penicillin-binding protein (PBP-2a or PBP-2′) (Utsui and Yokota 1985; Reynolds and Fuller 1986) that is not inhibited by β-lactam agents at clinically achievable concentrations and this new PBP can substitute for the cell's normal PBPs at concentrations of β-lactam agents that would normally be lethal to the cell (Archer and Niemeyer 1994; Berger-Bächi 1994). The drug of choice for these strains is often the glycopeptide antibiotic vancomycin. This inhibits peptidoglycan synthesis by binding to the terminal pair of D-Ala residues in the pentapeptide chain of the sugar–peptide cell wall precursor, sterically impeding its interaction with the transglycosylases which normally incorporate it into the peptidoglycan network. Unfortunately, resistance to vancomycin has emerged in the enterococci. The resistance mechanism is somewhat unusual in that it involves remodeling the pentapeptide of the cell wall precursor. The terminal D-Ala residue of the pentapeptide is changed to D-lactate. The loss of the amino group significantly reduces the affinity of the precursor for vancomycin. Because the D-lactate is cleaved from the precursor in the terminal stage of peptidoglycan synthesis, as the short peptide chains are joined together, the finished product is largely unaffected, although synthesis is slower. Remarkably, expression of vancomycin resistance can be inducible and the mechanism also involves signal transduction, mediated by what is known as a two-component regulatory system (see Hoch and Silhavy 1995). Two genes are involved, *vanS* and *vanR*. The former encodes a membrane protein, VanS, that senses the effect of the drug (Ulijasz et al. 1996) and records the fact by phosphorylating one of its histidine residues. The phosphate group is then transferred to an aspartate residue on the second component, VanR. This converts VanR to an activator specific for expression of the four genes needed for vancomycin resistance (Arthur and Courvalin 1993). A similar mechanism is used to regulate expression of virulence genes in *S.* Typhimurium and several other types of virulence gene (see Salyers and Whitt 2002). As if this degree of complexity were not sufficient, the whole system, vancomycin resistance and regulatory genes, is carried on a bacterial transposon, Tn*1546* (Arthur and Courvalin 1993). Recently, this form of vancomycin resistance has been detected in clinical strains of MRSA isolated in North America (Appelbaum and Bozdogan 2004), a worrying but not unexpected development because it has been shown in the laboratory that plasmids encoding vancomycin resistance transfer readily between enteroccocal strains and *S. aureus*. In addition, vancomycin resistance is evolving in *S. aureus* independently of acquisition of Tn*1546* or similar systems (Walsh and Howe 2002).

Many new antibacterial drugs have been introduced into clinical medicine in the last 25 years and plasmids conferring resistance to most of them have appeared within a relatively short time. Not only has the range of plasmid-determined resistance broadened but also more and more bacterial genera that carry resistance plasmids are being found (Tables 3 and 4). The appearance in the mid-1970s of plasmid-determined β-lactamase production, first in *H. influenzae* and then in *N. gonorrhoeae*, was of prime importance, not only to clinical

medicine where the strains presented a significant public health problem, but also to the study of plasmid evolution (Saunders et al. 1986; see also Chapter 25, Bacterial infections of the genital tract and Chapter 48, *Neisseria*), because some of the plasmids in both species were found to be closely related (Laufs et al. 1979). The TEM β-lactamase produced in both these organisms is encoded by a gene, *blaTEM*, carried on various transposons, among them Tn*1* and Tn*3* (Figure 7), which are widely distributed on plasmids. The production of a TEM β-lactamase by clinical isolates of a wide variety of gram-negative bacteria, particularly among the Enterobacteriaceae, of both human and veterinary origin, is common. Undoubtedly, the presence of this gene on a transposon, and its ability to transpose readily to many different plasmids, facilitated its rapid intergeneric spread. The route taken by such a resistance determinant, before it enters a particular bacterial species, may be circuitous, but if acquisition is desirable (i.e. of advantage to the survival of the organism), it is almost certainly inevitable. Indeed, reports indicate that transfer of resistance genes is not restricted to gram-positive–gram-positive and gram-negative–gram-negative exchanges, but can take place between gram-positive and gram-negative bacteria (Mazodier and Davies 1991), and even between bacteria and mammalian cells (Courvalin et al. 1995), although such events seem to be rare and any that do occur are likely to be nonproductive. Trieu-Cuot and Courvalin (1986) reported a kanamycin-resistance determinant encoding an APH(3′)III aminoglycoside phosphotransferase in a strain of *Campylobacter coli* identical to that previously found in streptococcal strains. For an account of antibiotic resistance in clinical practice, see Chapter 18, Antibacterial therapy.

Origin of resistance genes

The origin of resistance genes has been a puzzle for many years. Before the introduction of antibiotics these genes were rare, although plasmids similar to those now carrying resistance determinants were relatively common (Hughes and Datta 1983). Perhaps the most persistent and logical suggestion is that many of them originated in the antibiotic-producing organisms themselves, since these organisms, mostly streptomycetes, are sensitive to the antibiotics and so must necessarily protect themselves. This suggestion has been given credence by the finding that the amino acid sequences of several classes of the APH(3′) aminoglycoside phosphotransferases, which confer resistance to kanamycin and neomycin, from both gram-positive and gram-negative bacteria, are evolutionarily related to another from the neomycin-producing *Streptomyces fradiae* (Trieu-Cuot and Courvalin 1986). An interesting variation on this theme is that in the production of antibiotics, small amounts of DNA from the producing organism remain as a contaminant and this may be the source of some resistance genes seen in clinical strains (Webb and Davies 1993). Clearly, if true, this has considerable significance for future antibiotic production, particularly in terms of quality control measures.

Some, if not all, β-lactamases have probably evolved from the same ancestral gene(s) that produced the β-lactam targets, the PBPs. Recent work has clearly shown the evolutionary relationship between the class A β-lactamase of *Bacillus cereus* and a PBP from *Streptomyces* (Samraoui et al. 1986; Joris et al. 1988, 1991). Furthermore, Ghuysen and his colleagues have shown that the protein structures of several β-lactamases and some PBPs are highly conserved, strongly indicating an evolutionary link (Ghuysen 1991, 1994; Frère 1995). The branches from the ancestral gene that yielded present-day β-lactamases, on the one hand, and PBPs, on the other, almost certainly diverged a long time before the discovery of penicillin, let alone its use in clinical medicine (Massova and Mobashery 1999). Nonetheless, the evolution of β-lactamase genes continues to the present day (Galleni et al. 1995; Bush and Jacoby 1997; Koch 2000; Bradford 2001; Gniadkowski 2001; Ford and Avison 2004).

Although most clinically significant β-lactamases are plasmid-encoded and constitutively expressed (particularly in gram-negative bacteria), β-lactamases are also relatively common chromosome-encoded enzymes in many types of bacteria, not only those causing disease, and their expression can be elaborately controlled; some species even have multiple, coordinately controlled β-lactamases (Imsande 1978; Normark 1995; Rossolini et al. 1996; Hanson and Sanders 1999; Philippon et al. 1998). These findings suggest that protection against β-lactam antibiotics is a common and desirable property in nature, although high concentrations of β-lactam agents in the soil, or in other natural habitats, have not been detected. So, it is not at all clear from where the selection pressure for the evolution, particularly of the inducible β-lactamases, comes. An alternative suggestion is that, although β-lactamases hydrolyze β-lactams effectively, this activity is not the normal function of the

chromosomally encoded enzymes, some of which, if not all, may be involved in peptidoglycan metabolism (Morosini et al. 2000).

An equally intriguing case is that of trimethoprim. This is a purely synthetic compound that has no known natural analog. Its mode of action is to inhibit dihydrofolate reductase, which catalyzes one of the steps in folic acid synthesis (see Chapter 18, Antibacterial therapy). The enzymes in many bacteria are readily compromised by this antibiotic. Resistance to trimethoprim, e.g. as encoded by Tn*7* (Craig 1989), arises because of the acquisition of a gene encoding a dihydrofolate reductase that is much less sensitive to trimethoprim. The source of the gene is unknown. It may be one that naturally encodes a resistant enzyme; alternatively, it may be a mutant form of a naturally inhibited one. Several trimethoprim-resistance alleles, each encoding a dihydrofolate reductase, are now known (Huovinen 2001; Skold 2001). The speed with which resistance emerged, approximately 10 years after the introduction of the drug into clinical practice, is impressive and gives considerable cause for thought, because on an evolutionary time scale 10 years is but a blink.

The case of trimethoprim is not an isolated example. The emergence of resistance somewhere in the bacterial kingdom, following widespread use of a new antibiotic, and its subsequent dissemination among many bacterial species appears to be the norm rather than the exception, attesting to highly efficient gene transfer processes within populations of bacterial cells (Bennett 1995). The frequency of transfer does not need to be high to achieve efficient spread of a particular resistance gene. Even rare transfer events can be effective if environmental conditions impose a sufficiently strong selection pressure on those few progeny cells that do acquire the gene in question. The presence of the antibiotic in the cells' environment constitutes a powerful selective force. The few resistant cells will then rapidly reproduce, while the majority of their bacterial relatives are unable to do so, to become the dominant bacterial species. There is no reason to believe that the extensive interspecific gene transfer highlighted by the spread of resistance genes is confined to them. Rather, the view that all bacterial genes are potentially available to all bacteria is gaining more general acceptance, epitomized by the movement of some chromosomal β-lactamase genes on to plasmids and then into unrelated bacteria (Philippon et al. 2002; Walther-Rasmussen and Hoiby 2002; Bonnet 2004; Ford and Avison 2004), mediated by IS elements.

Resistance gene evolution by mutation

Resistance to an antibiotic may be the result of acquiring new genetic information in the form of a plasmid or transposon, or it may be due to a mutation in the gene for the antibiotic target that renders it less susceptible to the drug. For some drugs, e.g. streptomycin and rifampicin, this form of resistance is often readily selected in the laboratory; however, it is much less common in clinical experience, probably due in part to the success of plasmid–transposon systems and in part to the fact that alterations to key enzymes often come at a price (Andersson 2003). One clear exception to this is resistance to the fluoroquinolones, antibiotics that interfere with DNA synthesis through inhibition of enzymes called topoisomerases (Drlica and Malik 2003; Ruiz 2003; Sissi and Palumbo 2003). Here, resistance is acquired primarily by mutation of the GyrA component of DNA gyrase or of the ParC component of topoisomerase IV, or on occasion by a mutation that activates an efflux pump that removes the fluoroquinolones from the cell (Elliott et al. 2003; Eaves et al. 2004; Ricci et al. 2004).

There is one bacterial species for which acquisition of resistance by mutation is both the sole option and clinically significant, namely *Mycobacterium tuberculosis* in which plasmids appear to have little or no role to play (Cole and Telenti 1995). Multiple antibiotic resistance in *M. tuberculosis* is acquired by sequential accumulation of mutations in the genes encoding the antibiotic targets (Gillespie 2002; Wade and Zhang 2004). The apparent failure of *M. tuberculosis* to acquire R plasmids may reflect its unusually waxy outer surface that is markedly different from the outer surfaces of most bacteria (see Chapter 46, *Mycobacterium tuberculosis* complex, *Mycobacterium leprae*, and other slow growing mycobacteria).

Antibiotic synthesis

Plasmids determine the production of bacteriocins and microcins (Pugsley and Oudega 1987; see also Chapter 5, Bacteriocins and bacteriophages). They also play a part in the production of a variety of antibiotics, including

some of those used in medicine (Hopwood 1978; Chater and Hopwood 1989). Plasmid SCP1, in *Streptomyces coelicolor* determines production of the antibiotic methylenomycin. The same plasmid confers resistance to the antibiotic. Plasmids can carry structural or control genes determining production by *Streptomyces* of oxytetracycline, chloramphenicol, and perhaps other antibiotics. The genetics of antibiotic-producing microorganisms is of great interest and of enormous potential importance in the pharmaceutical industry, and rapid progress is now being made in this area (see, for example, McDaniel et al. 1995; Paradkar et al. 2003; Weber et al. 2003).

Resistance to other agents

Plasmids may also confer resistance to antibacterial compounds other than clinically useful antibiotics, such as a variety of metal ions and organometallic compounds. Plasmid-determined resistance to mercuric ions (Hg^{2+}) is very common in bacteria found in soil and water (Bale et al. 1987) such as *Pseudomonas* spp., in members of the Enterobacteriaceae and in *Staphylococcus* spp.; this is frequently linked to antibiotic resistance. In different surveys, 25–60 percent of R plasmids determined Hg^{2+} resistance. In general, high frequencies of antibiotic resistance are found in environments where antibiotic concentrations are high, e.g. hospitals and farms on which livestock are reared intensively. The apparent linkage of Hg^{2+} resistance stems, in part at least, from the finding that a family of large transposable elements encoding clinically significant antibiotic resistance, mediated via integrons, appears to have evolved from an ancestral element that encoded Hg^{2+} resistance. These transposable sequences seem now to be widespread, particularly among the Enterobacteriaceae (Grinsted et al. 1990). Mercury resistance linked to antibiotic resistance may also be perpetuated by the use of dental amalgams that incorporate mercury (Summers et al. 1993).

Mercury resistance is effected by reducing ionic mercury to the pure metal and releasing it in gaseous form (volatilization). The mechanism also involves active concentration of mercuric ions prior to reduction (Barkay et al. 2003). The complexity of the system suggests one of some antiquity rather than one of recent evolution.

Resistance to cadmium, lead, antimony, arsenic, tellurium, and silver compounds are plasmid-determined in staphylococci and gram-negative bacteria (Summers and Jacoby 1977; Summers and Silver 1978; Foster 1983; Silver and Phung 1996; Nies 2003; Silver 2003). Resistance to silver salts was first reported after the use in burns units of silver sulfonamide compounds (McHugh et al. 1975). Resistance to copper salts displayed by bacteria isolated on pig farms where copper is used as a feed additive has also been reported (Tetaz and Luke 1983; Brown et al. 1995). In these cases, the immediate selective conditions are obvious; however, when and where the resistance mechanisms evolved is another question. Resistance to heavy metal ions may be mediated by innate or acquired efflux pumps.

Plasmids may also change the sensitivity of their bacterial host to UV light and other mutagens (Mortelmans and Stocker 1976) and to bacteriocins (Pugsley and Oudega 1987).

The degradation of several toxic organic compounds, such as camphor, naphthalene, octane, and toluene, may be determined by plasmids, particularly in soil bacteria. These bacteria, often *Pseudomonas* or *Flavobacterium* spp., have evolved the ability to use these toxic compounds as nutrients. The use of these and similar bacteria to effect biological detoxification and reverse environmental pollution has been attempted, with some success, but this area of bacterial exploitation is still very much in its infancy (Shannon and Unterman 1993; Janssen et al. 1994; Spain 1995).

Virulence factors

Virulence determinants are genes, the expression of which is necessary for bacteria to establish and maintain an infection (see Chapter 6, Molecular basis of bacterial adaptation to a pathogenic lifestyle and Roth 1988; Dorman 1994; Salyers and Whitt 2002). They include colonization mechanisms, mechanisms to overcome host defense systems, and the production of toxins. All these functions may be encoded by plasmids (Brubaker 1985). For example, enterotoxin production in *E. coli* and *S. aureus* (Betley et al. 1986) and production of surface antigens by *E. coli* that allow colonization of the small intestine in specific mammals, including humans, can both be plasmid-determined (Brubaker 1985). At least one enterotoxin gene found in *E. coli* has been found on a transposon (Tn*1681*) (So and McCarthy 1980).

Strains of *E. coli* isolated from systemic infections in humans and pigs are more frequently hemolytic and more frequently produce colicin V than comparable fecal strains; both characteristics are plasmid-determined. Carriage of a ColV plasmid increases the virulence of *E. coli* strains for calves, chickens, and mice (Smith and Huggins 1976); however, the effect is not due to the colicin itself, but to other determinants encoded by the plasmid. The ColV plasmid encodes functions that facilitate the uptake of iron by the bacterial host (Williams 1979) and others that increase bacterial resistance to serum (Binns et al. 1979). Plasmids other than ColV also confer serum resistance on *E. coli* (Taylor 1983). In one instance this seems to involve the acquisition of an additional outer-membrane protein, which is a component of the plasmid transfer system (Moll et al. 1980). A plasmid that confers serum resistance on *Salmonella* Dublin has also been described (Terakado et al. 1988; Foster and Spector 1995).

The smooth to rough (S→R) variation in *S. sonnei* is accompanied by loss of the form I (S) antigen and loss of virulence. Kopecko et al. (1980) demonstrated that this conversion is determined by a large plasmid, loss of which results in the S→R change. Transfer of the plasmid to *S. flexneri* 2a or *Salmonella* Typhi generated derivatives that were agglutinable both by their own specific antisera and by antiserum specific to *S. sonnei* form I antigen. In *S. sonnei* the form I antigen, and hence the plasmid that encodes it, is one of the requirements for virulence (Chapter 54, *Salmonella*), as demonstrated in the Serény test.

Strains of *S. aureus* responsible for scalded-skin syndrome produce exfoliating toxins that, in some cases, are encoded by plasmids (Wiley and Rogolsky 1977). Some *Staphylococcus* spp. produce enterotoxins that cause the syndrome known as intoxicating staphylococcal food poisoning. Some of the toxin genes responsible for this syndrome are encoded by plasmids (Couch et al. 1988). Other examples of pathogenic properties determined by or associated with plasmids have been described and reviewed elsewhere (Elwell and Shipley 1980; Brubaker 1985; see also Dorman 1994; Salyers and Whitt 2002).

The role of R plasmids as possible virulence factors has been discussed by Elwell and Shipley (1980). Resistant bacteria, such as chloramphenicol-resistant *S.* Typhi, penicillin-resistant *N. gonorrhoeae*, or multiresistant *S. aureus* may sometimes appear to be of unusual virulence simply because the infections they cause do not respond to the first line of antibacterial therapy. This property certainly may facilitate dissemination, but does not necessarily imply increased virulence. Particular R plasmids may well have specific effects upon virulence, either increasing or decreasing it, depending on how expression of plasmid-encoded functions affects other virulence determinants. Indeed Lacey and Kruczenyk (1986) have argued that the plasmid-carrying MRSA, although posing an undeniable clinical problem, are not as virulent as their predecessors. However, generalizations in this area without rigorous experimental evidence are inappropriate and the spread of MRSA into the community would argue differently (Palavecino 2004).

In plants, *Agrobacterium tumefaciens* has long been known as the causative agent of crown gall, a tumorous disease that affects many plants and causes serious losses in fruit growing. The transformation to a tumor-like growth requires transfer from the bacterium to the plant cell of genetic information, part of which is incorporated permanently into the genome of the plant cell. The requisite information is encoded on large tumor-inducing (Ti) plasmids which mediate the transfer. This process is an elegant example of natural genetic engineering since the transformed plant cells produce compounds that can be used as nutrients by the *Agrobacterium* responsible for the transformation (Hooykaas 1989; Hooykaas and Beijersbergen 1994).

Metabolic characters

The metabolic diversity of the pseudomonads is due, in part, to the carriage of plasmids that specify degradation of unusual, often toxic, organic compounds, as already noted (see Harayama and Timmis 1989). Often, the metabolic genes are associated with, or are parts of, transposable elements (Tan 1999). 'Metabolic' plasmids have also been reported in other genera. When they are present in clinical isolates, such plasmids can initially complicate strain identification in the diagnostic laboratory. Lactose fermentation by strains of *Salmonella* (including Typhi) is usually plasmid-determined. Plasmids encoding lactose catabolism have also been found in isolates of *Proteus* and *Yersinia enterocolitica* (Falkow et al. 1964; Cornelis et al. 1976), and *Klebsiella* (Reeve and Braithwaite 1973), although in *Klebsiella* they are not prominent because the chromosome has a *lac* operon. In the study involving *Y. enterocolitica*, the particular genes were not only carried on a plasmid but were also transposable (Cornelis et al. 1978).

Genes for the utilization of other sugars, especially sucrose (*suc*) and raffinose (*raf*) may be plasmid-borne. Plasmids with both *lac* and *suc* genes have been found in *Salmonella* (Johnson et al. 1976), and *raf* genes are associated with those determining the K88 antigen adhesion factor which has been shown to be important in porcine *E. coli* enteritis (Shipley et al. 1978; see also Chapter 52, *Escherichia*). Plasmids determining H_2S production (Ørskov and Ørskov 1973), urease production (Farmer et al. 1977; Wachsmuth et al. 1979), or citrate utilization (Smith et al. 1978) have also been found in clinical isolates. Their preponderance is difficult to assess from phenotypic observation. However, modern molecular genetic techniques such as DNA probing, or PCR analysis, could possibly supply an answer, if needed. Such plasmids are not restricted to clinically important bacteria. Lac plasmids in *Lactobacillus lactis* cheese starter strains are of major importance to the dairy industry (Farrow 1980; see also Chapter 10, The microbiology of milk and milk products).

Phage inhibition

Carriage of certain plasmids can alter the susceptibility of the host to certain bacteriophages, thus changing the phage type of that particular isolate, which may be important in diagnostic and epidemiological investigations (Stanisich 1988). Usually the molecular basis for the change is unknown; however, some plasmids encode one of a class of DNA-degrading enzymes known as restriction endonucleases that fragment foreign DNA as it enters the bacterial cell, rendering it less susceptible to attack by some, if not all, phages. Such plasmids also encode the means to protect the host cell DNA, including the plasmid itself, from similar attack. This usually

involves methylation of particular bases within specific short sequences which are also the sites recognized by the restriction endonuclease (Primrose et al. 2001).

Mapping of plasmids

Because plasmids are small, relative to bacterial chromosomes, they are popular molecules with which to investigate numerous aspects of DNA metabolism, including replication mechanisms (Scott 1984), recombination (Dressler and Potter 1982; Hsu and Landy 1984) and gene expression (Primrose et al. 2001; Thomas 2000). This interest has led to the development of an impressive range of techniques designed to study DNA in general and plasmid DNA in particular (see Grinsted and Bennett 1988; Sambrook et al. 1989). In the past, electron microscopy has been employed extensively to analyze DNA molecules, both as a simple tool to estimate plasmid size and, by means of heteroduplex analysis (Burkardt and Puhler 1988), to examine DNA rearrangements such as insertions, deletions, replacements, and inversions. Electron microscopy has, however, largely been replaced by restriction enzyme analysis and, more recently, by DNA sequencing (Grinsted and Bennett 1988; Brown 2001; Primrose et al. 2001). This last technology has now evolved to the point where DNA sequencing of very large DNA molecules (e.g. human chromosomes) has been achieved. The complete sequences of many bacterial chromosomes, including several human and animal pathogens (e.g. *E. coli*, *H. influenzae*, *Mycoplasma genitalium*, and *Helicobacter pylori*) are now available, as are the complete sequences of several plasmids. These data allow individual genes to be identified and ordered on the plasmid and then to be cloned for further study. By means of in vitro mutagenesis, such genes can be systematically and deliberately altered (Braman 2002; Primrose et al. 2001; see also Watson et al. 1992). These mutations can then be analyzed for their effects in the same way as if they had occurred naturally (Grinsted and Bennett 1988; Brown 2001).

Evolution and classification of plasmids

Plasmids are found in most, if not all, bacterial genera. Their origins are a matter for speculation. Each bacterial genus or group of genera appears to have its set of plasmids. Host specificities of plasmids have not been much studied, with one or two notable exceptions such as RK2 (RP4) (Thomas and Smith 1987) and RSF1010 (Barth et al. 1981; Buchanan-Wollaston et al. 1987). However, R plasmids of *S. aureus* can replicate in *B. subtilis* (Ehrlich 1977) and some R plasmids in *E. faecalis* can transfer by conjugation to *S. aureus* (Engel et al. 1980) and to lactobacilli (Gibson et al. 1979). Plasmids found in the Enterobacteriaceae can usually be transferred between many, if not all, the genera within the family. Some transfer more widely. In general, plasmids resident in gram-positive bacteria appear not to be able to establish themselves in gram-negative bacteria and vice versa.

In classifying plasmids, host range might be expected to be an important criterion, but in practice it is not a very convenient one. When a newly discovered plasmid is not transferred to a new host in laboratory experiments it may be for any one of a variety of reasons, of which an inability to replicate in the new host is one. In practice, a much more convenient criterion is available. As already stated, certain pairs of plasmids cannot coexist stably in the same bacterial cell, a phenomenon termed incompatibility (Novick and Richmond 1965), which is expressed when two plasmids have the same, or very closely related, replication systems or partition systems, or both (Novick 1987). A strong incompatibility reaction generally indicates similarity in the former.

Replication systems and partition systems are not mutually dependent, and perfectly stable replicons with the replication system of one plasmid and the partition system of another can be constructed in the laboratory. In nature, however, it is likely that a particular replication system and a particular partition system will be found in association. Thus, two plasmids with essentially the same replication system are also likely to have related partition systems, reinforcing any incompatibility reaction.

When each plasmid in a collection is tested, in turn, against all others in the set, those which are incompatible can be identified and so the collection can be ordered into incompatibility (Inc) groups. This means of classification has been applied to plasmids in the Enterobacteriaceae, particularly *E. coli* (Jacob et al. 1977), in *Pseudomonas* spp. (Jacoby 1977), and in *S. aureus* (Novick et al. 1977). Plasmids that can replicate in both *E. coli* and *Pseudomonas* spp. are included in both classifications (Hedges and Jacoby 1980), for example, RP4 is IncP when in the Enterobacteriaceae but IncPI when in *Pseudomonas* spp.

Because it principally reflects the primary plasmid maintenance systems (replication and partition), incompatibility is a sound basis for grouping plasmids, and there is good evidence that it reflects evolutionary relationships. Within any one Inc group, plasmids, in general, show extensive DNA homology, i.e. common sequences are not restricted simply to replication and partition functions. By contrast, plasmids of different Inc groups rarely show extensive homology. Exceptions are plasmids of the IncF complex, which can be grouped into at least five Inc groups but which nevertheless display extensive homology because their transfer systems are closely related.

Plasmids that belong to the same incompatibility group in general encode the same or similar sex pili. By contrast, plasmids belonging to different Inc groups are more likely to encode sex pili that differ morphologically and serologically. Sex pili can act as receptors for

bacteriophages. One practical consequence of this is that pili can often be detected because they permit specific bacteriophage adsorption (Figure 13). However, because of the normally repressed nature of a number of plasmid transfer systems it may be necessary transiently to derepress a specific system before its identity can be established by the use of specific bacteriophages (Willetts 1988). In electron microscopy studies of their morphology and serology, Bradley (1980) identified pili determined by conjugative plasmids of many known Inc groups of *E. coli* and several of *P. aeruginosa*. His work shows that, with very few exceptions, all conjugative plasmids within an incompatibility group determine the same type of pilus, a finding consistent with conclusions from DNA homology studies.

Plasmids of the same incompatibility group often share a similar host range, show considerable DNA homology, are of similar molecular sizes, and, with conjugative plasmids, possess related transfer systems. By contrast, other plasmid-encoded properties, in particular antibiotic resistance, are not indicative of a particular incompatibility group. Most antibiotic resistance genes, which can be identified either as DNA sequences or as their protein products, are found on a wide variety of otherwise unrelated plasmids. It seems that present-day plasmids have evolved, and continue to evolve, by the accretion of DNA sequences of transient or lasting value to bacterial cells. These sequences are often components of bacterial transposons and integrons (Wiedemann et al. 1986; Hall and Collis 1995; see also Levy and Novick 1986; Berg and Howe 1989; Thomas 2000).

It is often stated that R plasmids consist of a resistance transfer factor (RTF) (a conjugative plasmid component) linked to a resistance determinant (r-det). The reason is historical (see Novick 1969; Helinski 1973) because the earliest studies of R plasmids involved members of one incompatibility group, IncFII, which display precisely this form. In the light of more diverse studies, it can be seen that the description is specific rather than general and many R plasmids have structures that do not conform to this simple compartmentalized scheme, e.g. RP1 (Figure 14) (Gorai et al. 1979; Villarroel et al. 1983; Thomas 1989).

BACTERIAL VARIATION AND EPIDEMIOLOGY

In epidemiological studies, the aim is to identify a particular clone within a bacterial species in order to trace its spread and, if possible, to determine its origin. In the past, biochemical and serological characters, phage sensitivities and lysogeny, production of or sensitivity to bacteriocins, sensitivity or resistance to antibiotics and other antibacterial agents, and plasmid profiles have all been exploited to this end. These characters are usually sufficiently stable to be useful when tracing bacterial strains over relatively short periods, but it should be remembered that none of them is immutable and several are encoded by extrachromosomal elements which may be lost over a period of time. Furthermore, new characters can be acquired by acquisition of a plasmid or a transposon. The isolation of variants indicates either genetic change in an epidemic strain or the discovery of a different strain of the same species. It is not always possible to distinguish between these alternatives (Seal et al. 1981), but the more characters used to identify the strain, the greater the chance that these alternatives can be distinguished. Today, molecular genetic techniques such as pulse-field gel electrophoresis (Gardiner et al. 1986; Morrison et al. 1999; Arakawa et al. 2000; Cohen et al. 2001) and multilocus sequence typing (Enright and Spratt 1999; Clarke 2002; Urwin and Maiden 2003; Cooper and Feil 2004) are assuming greater prominence in strain typing. However, these techniques are still technically demanding and relatively expensive, so serological, biochemical, and phage typing systems are still commonly used in the diagnostic laboratory.

Chromosome analysis

With the development of automated high throughput DNA sequencing systems, it has become possible to

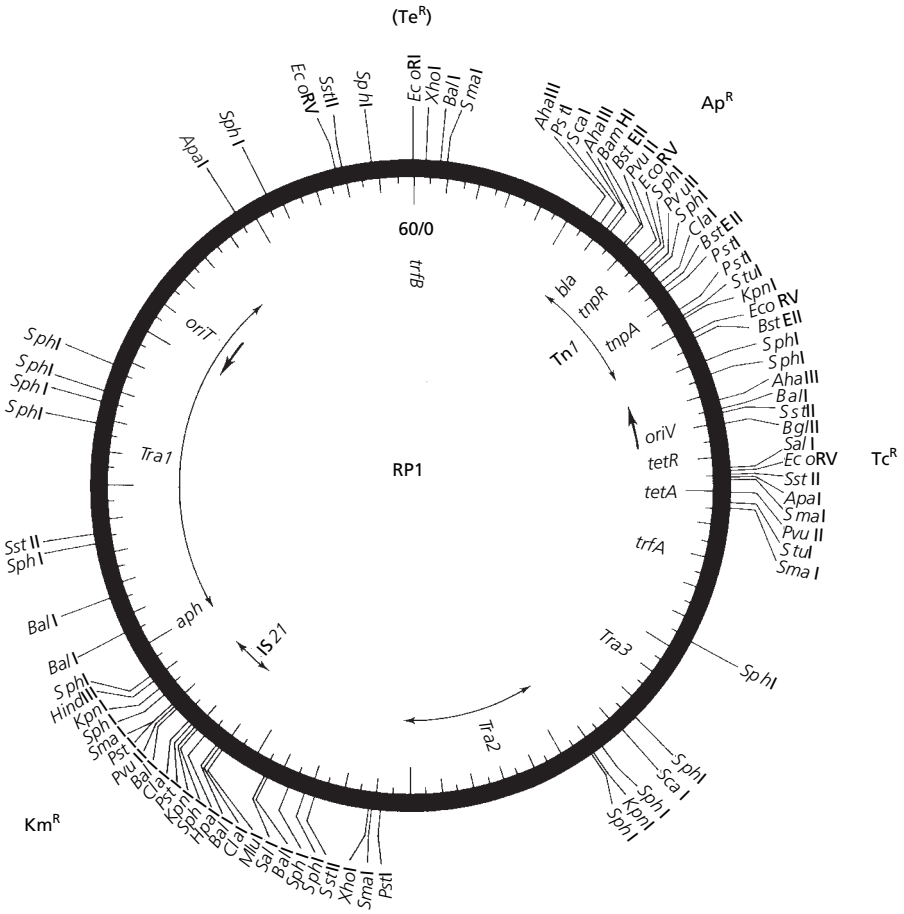

Figure 14 *Restriction and genetic maps of RP1. Plasmid RP1 is a 60 kb IncP conjugative resistance plasmid conferring resistance to ampicillin (Ap), kanamycin (Km), and tetracycline (Tc) that was isolated from a strain of* P. aeruginosa. *Genetic loci:* aph*, aminoglycoside phosphotransferase (resistance to kanamycin and neomycin);* bla*, TEM-2 β-lactamase (resistance to β-lactams including ampicillin and carbenicillin);* tet*, tetracycline resistance genes;* oriT*, origin of conjugative transfer;* Tra*, genes required for conjugative transfer;* oriV*, origin of replication;* trf*, plasmid replication genes;* tnp*, transposition genes of Tn*1 *(Figure 5). The map is redrawn, with permission, from Thomas and Smith (1987).*

sequence entire bacterial chromosomes in a matter of months. Activity in this field has been intense in the last few years and now more than 200 have been completed, with more than 500 in progress (www.genomesonline.org). Analyses of these sequences has led to the realization that most, if not all, bacterial chromosomes are mosaic structures (Lawrence and Roth 1999), comprising a backbone sequence, in which all the genes appear to derive from a common phylogenetic origin, and multiple inserted sequences from diverse sources, such as IS elements, transposons, ICEs, bacteriophage genomes, and genomic islands acquired by horizontal gene transfer.

A subset of genomic islands, detected first in human pathogens and then subsequently in animal and plant pathogens, contains genes for bacterial virulence. These genomic islands are called pathogenicity islands (PAI) (Hacker and Kaper 2000). The origins of some of these are more evident than others in that they are clearly lysogenic phages or their remnants. Examples of virulence genes that are phage components are the cholera toxin genes of *V. cholerae* and the shiga toxin genes of *S. dysenteriae* (Waldor and Mekalanos 1996; Waldor 1998). PAIs encode a diversity of virulence determinants, such as adherence and invasion factors, iron uptake systems, protein-secretion systems, as well as bacterial toxins. Such genomic islands tend to be relatively large sequences (10–200 kb) and are often flanked by short direct repeats reminiscent of the result of site-specific recombination or transposition (Davis and Waldor 2002). Indeed, among the gene complement of a PAI are often found genes encoding putative transposases and integrases. A few PAIs have been shown to be mobile, and in some cases movement has undoubtedly been phage mediated, e.g. PAIs found in *S. aureus* and *V. cholerae* (Lindsay et al. 1998; Karaolis et al. 1999). In the case of the former organism, capture of the PAIs called SCCmecs generates MRSA strains (see above).

It is worth comment that it is possession of different PAIs that distinguishes enterohemorrhagic, enteropathogenic, and uropathogenic *E. coli* from avirulent strains and from each other (Hacker and Kaper 2000). For a more detailed and elegant discourse on the molecular genetics of a variety of human bacterial pathogens, see Salyers and Whitt (2002).

GENETIC MANIPULATION IN VITRO

Molecular genetics, especially recombinant DNA technology (or genetic engineering), provides powerful tools with which to analyze any genetic system. These techniques make it possible, in principle, to isolate any gene from any cell type and manipulate it so that it can be expressed in a bacterial cell such as *E. coli* and then return it, perhaps in a modified form, to the cell line of origin. Gene cloning is undertaken for two primary purposes: to allow the isolation of a desired fragment of DNA in quantities suitable for sequencing, and to enable the experimenter to insert a gene of interest into a suitable cell line where its expression can be studied or in which the gene product is produced in large amounts, so facilitating its isolation and purification.

The bacterial chromosomes of *E. coli* and similar bacteria contain almost 5×10^6 bp. In a human cell the DNA is packed into 46 chromosomes, each containing about $3\,000 \times 10^6$ bp. The problem is, therefore, how one gene a few thousand bp in length can be recovered from such a mass of DNA. Until the mid-1970s such a feat was not possible. This situation was changed by the discovery of the class of DNA endonucleases (type II restriction enzymes) (Primrose et al. 2001) that cleave double-stranded DNA at specific nucleotide sequences, cutting it into much smaller linear pieces that can then be recovered and identified. The target sites for these enzymes normally comprise 4, 5, or 6 bp of specific sequence and are usually rotationally symmetrical, often termed palindromic because the sequence of the site read in the 5′ to 3′ direction on one strand is the same as that read in the 5′ to 3′ direction on the opposite strand (Figure 15). There are two ways in which these enzymes cut double-stranded DNA. Some cut at positions on the DNA strands opposite each other, giving 'blunt' or flush ends. Others give a staggered cut, producing short single-stranded extensions (Figure 15) that, because they are generated from palindromic sites, are the same. Fragments generated by type II restriction enzymes (restriction fragments) can be joined together in vitro by DNA ligase. Ligation of fragments with single-stranded extensions generated by the same restriction enzyme proceeds more efficiently than ligation of fragments with flush ends because the complementary nature of single-strand extensions, sometimes called 'sticky ends,' encourages fragments to align end to end, so facilitating the ligation reaction. The most commonly used ligase commercially available is that encoded by phage T4. After manipulation in the test tube, desired recombinant DNA molecules are recovered by transformation of a suitable bacterial host. The formation of novel hybrid DNA molecules in vitro, coupled with their recovery and amplification in bacteria, is termed cloning (for a more detailed exposition, see Brown 2001; Primrose et al. 2001).

Cloning vectors

To be perpetuated, cloned genes must become part of a DNA molecule that is replicated in each division cycle. There are two convenient types of genome that can be used for cloning – plasmids and bacteriophages. In bacterial genetics the most commonly used plasmid cloning vectors are small, multicopy plasmids. Many are derivatives of two early vectors, pBR322 and pACYC184 (see, for example, Thompson 1988), constructed in the laboratory from small natural plasmids, pMBI and pl5, respectively. They have been manipulated to possess several desirable features not present on the original elements, such as a choice of suitable cloning sites (preferably associated with insertional inactivation) and a convenient and reliable marker for selection (usually a drug resistance gene); for example, one of the first cloning vectors, pBR322, has approximately 4 200 bp and single sites for a number of restriction enzymes, including *Bam*HI, *Hin*dIII, *Pst*I, and *Sal*I. The single *Pst*I site is within the ampicillin resistance gene which encodes a β-lactamase. Cloning into this site results in the loss of ability to confer resistance to several β-lactam antibiotics, including ampicillin, i.e. cloning into this site causes insertional inactivation of the Amp resistance determinant. Hence, clones containing recombinant plasmids are recognized because

they acquire resistance to tetracycline but not to ampicillin. Similarly, cloning into the single *Bam*HI, *Hin*dIII, or *Sal*I sites creates recombinant plasmids that confer resistance to ampicillin but not to tetracycline.

The next incarnation of pMB1-derived cloning vectors, and one that has stood the test of time, up to the present day, was the pUC series of vectors, whose qualities are best displayed by pUC18, a vector commonly chosen for shotgun cloning for genomic sequencing projects. The size of the vector was reduced by removing the tetracycline resistance gene from pBR322, together with the *rop* region, the function of the latter being to control plasmid copy number. This single change increased the copy number more than 10-fold, greatly facilitating preparation of large amounts of the vector, and improved the transformation efficiency. Then a copy of the sequence encoding the N-terminal 145 amino acid peptide of LacZ (β-galactosidase), the alpha- (α-)peptide, that had previously been subject to in vitro mutagenesis to introduce a set of unique restriction endonuclease sites into the α-peptide coding region, the multiple cloning site (MCS), while retaining α-peptide function was inserted. In a host that produces the remainder of the β-galactosidase protein, the omega- (ω-) peptide, α-complementation occurs to give a functional β-galactosidase. The basis for the screen is the ability of β-galactosidase to hydrolyze the chromogenic substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside, known as Xgal, to produce a deep blue, poorly diffusible product. When α-complementation occurs, i.e. the cell produces both the α- and ω-peptides, which combine to create functional β-galactosidase, the colonies are dark blue on agar containing Xgal. In contrast, cells in which there is no α-complementation fail to produce β-galactosidase and the colonies are white on Xgal-containing media. This allows ready identification of vectors containing inserts, because cells carrying such constructs fail to produce a functional β-galactosidase and the colonies are white. The process is referred to as blue-white selection, but it should be noted that the selection refers to experimenter choice, not use of a selective medium. A major strength of the system is that the distinction between blue and white can easily be made on the same plate, so no replica plating is required. Indeed, during construction of a genomic library using pUC18, blue/white screening is used simply to confirm that a high proportion of vectors in the library have inserts. One further development was the replacement of the ampicillin resistance marker of pUC18 with a kanamycin resistance gene to give pK18 (Pridmore 1987) for use when ampicillin selection is inappropriate.

Phages and genetically modified variants are also used extensively as vectors in genetic modification (cloning) experiments in *E. coli* and other organisms (Primrose et al. 2001). Two that have proved useful in this respect are the single-stranded DNA phage M13 (Messing 1991) and the double-stranded DNA phage λ (Brammar 1982), both parasites of *E. coli*.

Phage M13 has a 6.4 kb genome in which a 507 base intergenic region can be used for the introduction of up to 1.5 kb of cloned material. The great value of this particular phage is that, although it replicates as a double-stranded element that can be introduced into a host cell in the same way as plasmids are introduced by transformation (a process termed 'transfection'), its DNA, when packaged, is single-stranded – an ideal element for DNA sequencing and some mutagenesis procedures in vitro (Messing 1991).

Phage λ has a much larger genome (52 kb) than M13 (Arber 1983; Brammar 1982) and, by deleting the inessential integration functions and also sequences in the b2 region, it is possible to accommodate up to 25 kb of cloned DNA into the residue of the phage genome. One consequence of the large genome size is that there are several copies of all the common restriction endonuclease cut sites, so a further step in the design of λ cloning vectors was to remove all but one or two of each; this was accomplished by in vitro mutagenesis and also by selection of variants grown in a host that forms the endonuclease concerned. Two types of λ vector are in common use. Insertion vectors have a unique site (usually *Eco*RI) into which the DNA is cloned, thus inactivating the gene in which the site lies and allowing detection of the vector whose gene is inactivated; λ NM607 has such a site within the *cI+* gene which, when inactivated, eliminates the immunity function and gives clear plaques (Brammar 1979), and members of the λgt11 series (λgt11–λgt23) and λZAP have that part of the *lacZ* gene which encodes the alpha fragment of β-galactosidase and can thus be used in blue-white plaque selection using X-gal (Chauthaiwale et al. 1992). In replacement vectors there are two endonuclease-sensitive sites and the region lying between them is replaced by the material to be cloned (e.g. the λcharon series 4A, 32, 35, 40, and λEMBL3, λEMBL4) (Chauthaiwale et al. 1992). The efficiency of the subsequent transfection step can be improved by utilizing a packaging procedure in vitro rather than introducing the entire vector molecule into its host (Primrose et al. 2001). A further development of λ as a cloning agent is the cosmid (Collins and Bruning 1978). This is a hybrid between λ and a plasmid, in which λ contributes the region containing its cohesive ends and the plasmid supplies an origin of DNA replication together with a gene that allows selection of the desired clone (Wahl et al. 1987). Cosmids do not contain the λ sequences needed for DNA replication and particle maturation and hence there is room for far more DNA to be cloned (up to about 40 kb). The recombinant molecules are packaged in vitro to produce transducing particles which are used to deliver the vector and its insert into a suitable strain of *E. coli*. The cosmid system has been used to construct genomic libraries of several organisms, a set of recombinant clones that between them contain all the DNA present in an individual organism (see, for example, Goodman

et al. 1995; Jacobs et al. 1991; Little 1992). Among the phages specific to other organisms, the λ-like ϕC31 of *Streptomyces* has been used as the progenitor of several cloning vectors (see Pritchard and Holland 1985; Rodicio et al. 1985; see also Primrose et al. 2001).

Specialist plasmid cloning vectors

If a vector has been engineered to carry two origins of replication to allow it to be maintained in at least two different organisms, then it is called a shuttle vector, i.e. one origin supports replication in one cell type while the second supports replication in the other. Such vectors usually carry an origin of replication appropriate to *E. coli* (e.g. from pMB1), a selectable marker such as ampicillin resistance, also appropriate to *E. coli*, together with the *lacZ* α-sequence and multiple cloning site from pUC18, and a selectable marker for the second cell type. The point of incorporating these features is that recombinant plasmids, produced in vitro, can first be recovered by transforming *E. coli*, so maximizing transformation efficiency. Then, large amounts of the correct recombinant plasmid can be purified and used to transform the other target host. Using shuttle vectors, genes can easily be recovered in *E. coli* and then introduced into, for example, a human cell line (where the second origin of replication on the cloning vector often comes from the monkey virus, SV40, which can replicate in human cells), or plant or yeast cells. The purpose of shuttle vectors is to exploit the plethora of molecular genetic techniques that can be used with *E. coli* systems to recover and manipulate DNA sequences before reintroducing the particular sequence into the original cell line or an appropriate surrogate, where the effects of mutation or overexpression can be determined. When coupled with the use of expression systems (below), shuttle vectors can be used to overexpress a protein in a different background, when overexpression in *E. coli* is problematic.

Fulfilling a similar role to shuttle vectors, but generally limited to bacterial systems, broad host range bacterial vectors have a single origin of replication that can be used in many phylogenetically diverse bacteria. Broad host range vectors were originally derived from naturally occurring broad host range bacterial plasmids, which encode their own replication proteins that recognize their own origins of replication (see, for example, Bagdasarian et al. 1981; Morales et al. 1991). As long as the genes encoding the vector-specific replication proteins can be expressed in the target host, the vector will replicate. Broad host range vectors are, by necessity, larger than pUC18, but they have been modified over the years to reduce their size and in some cases, the origin of replication, *lacZ* α-peptide sequence and multiple cloning site from pUC18 have been added to facilitate initial manipulation of the vector in *E. coli*, so optimizing recovery of the sequence of interest, since many potential target bacteria are difficult to transform. Then, sufficient quantities of the correct recombinant plasmid can be produced to facilitate transformation of the final host. In some instances the recombinant plasmid can be mobilized into the final recipient by conjugation from the *E. coli* donor because the vector has also been supplied with an origin of transfer and the functions specific to it. The bulk of the transfer system is usually provided by a helper conjugative plasmid also present in the transformant.

Plasmid vectors for recovery of PCR amplicons

PCR is now the method of choice if what is needed is simple amplification of a DNA fragment. However, PCR cannot easily be used to amplify a section of DNA if the sequences at the ends of the fragment to be amplified have not been determined. Furthermore, to sequence a PCR amplicon is more difficult than to sequence the insert of a recombinant plasmid, particularly if it is more than 1 kb in length. Thus, PCR is generally used to amplify specific, small, known sequences of DNA, for surveys of sequence heterogeneity, and for more complex in vivo techniques, such as allelic replacement by homologous recombination (see below). As a preliminary to these more complex techniques, it is firstly necessary to insert the PCR amplicon into a cloning vector. PCR amplicons are linear, double-stranded molecules, and those produced using the most common form of *taq* DNA polymerase carry single adenine overhangs at the 3′ end of each DNA strand, generated by the inherent terminal transferase activity of DNA polymerase. These adenine residues complicate the task of inserting the PCR product (amplicon) into a cloning vector because they first have to be removed before the fragment can be blunt-end ligated into the vector. However, cloning vectors based on pUC18 are now available where the multiple cloning site contains a restriction site that, when cut, generates single T overhangs at the 3′ end of each strand (for example, see Marchuk et al. 1991). Thus, the PCR amplicon can be ligated directly into the vector, without the need to remove the A overhangs from the amplicon. Once ligated into the 'TA cloning vector,' for example pCR2.1, and replicated in *E. coli*, the insert can subsequently be removed by cleavage at other restriction sites within the multiple cloning site and subcloned into a more specialist vector.

Plasmid vectors for overproduction of proteins in vivo

Modern biochemical studies and biotechnological processes often require large amounts of a particular protein, and the most efficient way to produce proteins

in large quantities is to overexpress recombinant genes in vivo. As with so many other molecular biology processes, *E. coli* was the first to be investigated as a surrogate host for protein production. Gene expression in *E. coli* requires an appropriate promoter sequence to allow transcription of the gene into mRNA, a ribosome binding sequence (RBS) to allow translation of the gene transcript, and an ATG start codon to initiate translation. It is sometimes possible to express a recombinant gene in *E. coli* simply by inserting it, together with its natural promoter, RBS and ATG start codon into a standard cloning vector such as pUC18 and transforming the construct into *E. coli*. In this case, the fact that pUC18 has a copy number of 50–100 relative to that of the *E. coli* chromosome means that the gene of interest can be expressed at levels well above that of a single copy gene. However, this approach is somewhat hit and miss. For many reasons, the expression of a cloned gene may not be optimal in the surrogate host. Because of phylogenetic drift, promoters, RBS sequences, and initiation codons associated with genes not native to *E. coli*, particularly those from eukaryotes and very different bacteria, may not be recognized by the *E. coli* RNA polymerase and ribosomes.

If the promoter or RBS associated with a cloned gene is not active in *E. coli* then, irrespective of the copy number of the recombinant vector, the gene will not be expressed. In such cases, a specialist expression vector can be used, for example one of the pET series of vectors, to provide an optimal *E. coli* promoter, an RBS, and, when necessary, an initiation codon upstream of the inserted gene to promote high-level expression (Studier et al. 1990).

Perpetual high-level expression of a recombinant gene in *E. coli* is rarely successful. For the bacterium to divert large amounts of energy into the production of a single protein tends to be debilitating to the organism as a whole. Furthermore, the presence of large quantities of 'foreign' protein often results in it being sequestered in insoluble aggregates or degraded, thus reducing overall yield. In some cases, the foreign protein directly disrupts the cell's normal physiology, and is said to be toxic. If toxicity is extreme, it may not be possible to transform the surrogate cell with a recombinant plasmid from which the gene encoding the toxic protein is constantly expressed. To help overcome the problems noted above, and to maximize protein yield, it is necessary to control gene expression. This is usually achieved by using an inducible promoter to drive transcription of the cloned gene. This strategy ensures a minimal level of transcription, and hence protein production, during normal cell growth, and allows the cell line to be cultured, but provides the means rapidly to increase production of the protein when the culture has attained a suitable cell density, thus generating large amounts of the protein. That this will also kill the cells is not important, because they are necessarily killed when the protein is harvested.

Many different transcriptional regulatory systems have been characterized, which it would be possible to adapt for incorporation into an expression vector. However, two inducible promoters dominate the field and their regulatory systems were among the first to be discovered. The most common is a derivative of the *E. coli lac* operon promoter, called *ptac*. This is a high efficiency, naturally generated hybrid promoter which is controlled by the *lac* operon repressor, LacI (de Boer et al. 1983). In the absence of an inducer (usually the gratuitous inducer isopropyl-β-D-galactopyranoside (IPTG)) promoter activity is shut off. However, repression is not complete and some escape synthesis of mRNA does occur, resulting in low-level expression of whatever gene is coupled to the promoter. For many cloned genes this level of control is adequate, but for a few even a low level of expression is potentially damaging. In these cases an alternative expression system is necessary.

Some expression vectors (e.g. the pET series) include a stylized promoter, which is recognized by the RNA polymerase of the *E. coli* bacteriophage T7 and not by the *E. coli* RNA polymerase. Regulated expression from this promoter is achieved by regulating production of the T7 RNA polymerase itself. To this end, an *E. coli* cell line carrying the T7 RNA polymerase gene, expression of which is driven by the *ptac* promoter, is used, e.g. BL21 cells (Dumon-Seignovert et al. 2004). Growth of BL21:pET in nutrient broth without IPTG allows little or no expression of the gene cloned into pET, because, whilst repression of transcription at the *ptac* promoter controlling production of the T7 RNA polymerase is leaky, the level of T7 RNA polymerase in the cell is never sufficient to activate transcription of the cloned gene from the T7 promoter. T7 RNA polymerase production is switched on when desired by addition of IPTG to the growth medium, when expression of the cloned gene is also triggered. To enhance production of the desired protein, once the cell has produced T7 RNA polymerase, the antibiotic rifampicin can be added to the medium. This inhibits the *E. coli* RNA polymerase, but not T7 RNA polymerase. So, whilst addition of rifampicin stops any further production of T7 RNA polymerase, because it blocks transcription of all *E. coli* genes by inhibiting the cell's own RNA polymerase, it stimulates transcription by T7 RNA polymerase by eliminating a major competitor for the substrates of RNA synthesis. With this strategy the cell is converted to one that synthesizes only the protein encoded by the cloned gene driven by the T7 promoter.

The second major regulatory system to be exploited for cloning vector development is the Ara system of *E. coli*, which is involved in metabolism of the sugar arabinose (Lee et al. 1974). In this system, a transcriptional activator, AraC, acts on the promoter controlling expression of the *araBAD* operon to enhance RNA polymerase binding and so promote transcription of the operon. Binding of AraC close to the promoter is

absolutely dependent upon arabinose. When there is no arabinose in the cell, the *araBAD* promoter is silent. Genes cloned downstream of the *araBAD* promoter in expression vectors incorporating the *araC* gene, e.g. pBAD (Guzman et al. 1995) are only expressed in the presence of arabinose, and expression is completely shut off in the absence of the sugar, thus minimizing problems associated with toxic protein production.

High-level expression of some proteins in *E. coli* can be difficult to achieve, particularly if the proteins are normally functional in a eukaryotic cell. One reason for this is that eukaryotic proteins are often modified post-translationally; for example, they are processed to remove signal tags associated with protein targeting, or they have molecules added to their backbones, e.g. glycosylation. Without the correct modifications, the protein may lack activity and may even be degraded because it cannot fold properly. The solution to this problem is to express the protein in a eukaryotic host that can perform the required modifications. For this, a shuttle vector is used, which has the necessary promoter and translation signals for expression in the surrogate host, such as insect cells or *Xenopus* oocytes.

Plasmid vectors that allow targeted modification of chromosomal genes

Once a DNA sequence encoding a particular protein has been identified, it is possible to make targeted changes to the DNA, and then determine the effects of such changes on the activity of the protein product. Targeted changes include deletions, truncations, or point mutations in the gene, or in its promoter/operator sequences. Mutations can easily be introduced using PCR technology, as described earlier in the chapter. However, in order to determine the biological significance of a particular mutation, it is necessary to put the mutant gene into the original organism. If the mutant gene phenotype is dominant over that of the chromosomal wild-type allele, this experiment can be performed simply by transforming the original cell line with an appropriate construct carrying the mutant gene. However, in most cases, mutant alleles are recessive, even when present in multiple copies, and their presence is masked by the dominant wild-type chromosomal copy. In this case, the wild-type allele must be replaced with the mutant allele, a procedure termed allelic replacement, using homologous recombination.

Gene replacement by homologous recombination

Homologous recombination involves exchange between two very similar sequences of DNA (Eggleston and West 1996). If a gene knockout is needed, a modification of site-directed mutagenesis can be used to avoid the need to clone the gene of interest when preparing DNA fragments for allelic gene replacement. Multistage PCR is used to create a DNA fragment carrying a version of the gene with a suitably located restriction site (see above). The fragment is cleaved with the restriction endonuclease and the two pieces are ligated to a third fragment encoding an antibiotic resistance gene. This ensemble can then be amplified by PCR to produce ample DNA to use directly to transform the cell line of interest, selecting for antibiotic resistant transformants. To maximize the frequency of transformation, electroporation is used to introduce the mutant allele of the gene of interest into the cell. The desired transformants are created by a double crossover between homologous sequences on the introduced DNA fragment and on the bacterial chromosome, one within each gene segment flanking the antibiotic resistance gene (Datsenko and Wanner 2000). This recombination exchanges a section of the chromosomal gene for its equivalent on the fragment including the interpolated antibiotic resistance gene. The drawback to this technique is that most bacteria are not easily transformed by linear DNA fragments. The fragments tend to be degraded rapidly once inside the cell. To circumvent this problem, the DNA fragment can be circularized before it is used to transform the cell. One way to do this is to clone the mutant allele and then use the recombinant plasmid to effect the transformation. When such a construct is put into a cell, then a single crossover within the sequence common to the recombinant plasmid and the chromosome will fuse the recombinant plasmid with the chromosome, generating in the process a direct duplication of the homologous sequence. A second crossover within the duplicated region, but at another point, will reverse the integration, leaving behind in the chromosome part of the cloned fragment while the equivalent part of the chromosomal copy becomes part of the excised plasmid, thus transferring the mutant allele to the chromosome. However, the system only works efficiently in practice if the recombinant plasmid is unable to replicate in the cell to be mutated (otherwise, excisions that essentially regenerate the mutant allele on the free recombinant plasmid and reconstitute the original chromosomal copy of the gene cannot be distinguished phenotypically from the desired mutants). This problem has been solved by the development of suicide vectors, i.e. cloning vectors that can be propagated only in special cell lines (permissive) and which otherwise are not maintained as extrachromosomal elements (Datsenko and Wanner 2000).

Suicide vectors

Because suicide vectors are designed not to be maintained in most cells, when the DNA is electroporated into cells it will persist simply as nonreplicating circles of DNA, unless rescued by integration into one of the

replicons in the cell. There are many such vectors, which all work in a similar manner, for example pKNG101 (Kaniga et al. 1991) and the pEX18 series of suicide vectors (Hoang et al. 1998). Each of these vectors carries a multiple cloning site, which allows insertion of a mutant allele of the gene of interest. They also possess the R6K origin of replication, ori_{R6K}, which will only function in cells that possess the R6K *pir* gene (Kolter et al. 1978), usually provided in *E. coli* by lysogenization with a specialized λ*pir* transducing phage. In addition, each vector is provided with a selectable marker gene, usually an antibiotic resistance gene, and a copy of the *B. subtilis sacB* gene. This last feature allows selection of derivatives that have lost the suicide vector, because expression of *sacB* is lethal when cells are exposed to sucrose. Finally, each also carries the transfer origin of the conjugative resistance plasmid RK2, which allows the construct to be mobilized easily by conjugation into the target cell line.

When the target host (nonpermissive) is mated with a *pir+ tra+ E. coli* (permissive host) carrying the pEX18 recombinant and a conjugative helper plasmid, the suicide vector and its passenger gene is transferred to the recipient. However, the antibiotic resistance encoded by the plasmid is only acquired if the plasmid is maintained, which is not possible if the plasmid remains autonomous. Accordingly, in order to be replicated, the cloning vector must be rescued by integration into the genome of the recipient cell. This normally occurs by homologous recombination between the cloned gene on the pEX18 recombinant and its homolog on the chromosome. This integrates the plasmid into the chromosome generating an arrangement where the suicide vector is sandwiched between two copies of the target gene, one of which is disrupted by the antibiotic resistance gene cassette. This first recombination event is rare, but because of the plasmid marker, the small number of bacteria carrying the integrated plasmid can easily be selected.

Derivatives with the chromosomally integrated pEX18 recombinant plasmid are then cultured in antibiotic-free medium, if necessary for several passages, to allow a second crossover between the two copies of the target gene. This excises the vector and one copy of the target gene from the chromosome. The excised sequence is lost as the cell multiplies, leaving a single chromosomal copy of the target gene. In a proportion of the derivatives the remaining copy of the target gene will be disrupted by the antibiotic resistance gene cassette. These are easily selected on medium containing sucrose, which kills all those cells that still carry the suicide vector, and the appropriate antibiotic, which kills all those that no longer possess the antibiotic resistance cassette used to disrupt the target gene.

One problem with this technique is that the mutation marker, i.e. the antibiotic resistance gene, remains in the chromosome, so the same antibiotic resistance gene cassette cannot be used to disrupt another gene in the same bacterium. To counter this problem, resistance cassettes have been developed that are flanked by specific recombination sites, so that the antibiotic resistance gene cassette can be excised by the appropriate site-specific recombinase. An inducible form of the gene for this enzyme is introduced into the cell on a helper plasmid and once the allelic replacement has been effected, expression of the recombinase is induced. Removal of the cassette is achieved in such a way that a frameshift mutation is generated in the gene of interest (Datsenko and Wanner 2000).

The technique can also be used to introduce mutations other than antibiotic resistance gene cassettes. Mutant genes are created by site-directed mutation as normal and the fragment inserted into an appropriate suicide vector. Then, the only modification to the final stages is that selection is for sucrose-resistant derivatives only. These are then screened for those carrying the mutant allele of the gene, because only approximately one in two will carry the mutant allele. Screening by change of phenotype may be possible; alternatively, the target gene is recovered by PCR amplification from the chosen clones, the fragments are sequenced and the mutants identified. The major advantage of this approach is that it can be used repetitively to introduce targeted point mutations into different genes of the same cell line or multiple mutations may be introduced sequentially into the same gene.

Transposon-delivery vectors for random insertional inactivation of chromosomal genes

Throughout the history of bacterial molecular genetics, the isolation of loss of function (null) mutants with easily detected phenotypes has been used to study the genetic basis of the particular phenotype. The main reason for selecting null mutants is to locate the mutated gene, and to confirm a role for that gene in a particular phenotype. A classic example is the selection of *E. coli lacI* null mutants, in which production of β-galactosidase is derepressed, i.e. lacZ is expressed at high level irrespective of the provision of an inducer such as IPTG. Although recovery of such mutants is relatively straightforward, locating the site of the mutation, and therefore the *lacI* gene, is somewhat more complicated. Originally this was achieved by classical bacterial genetics using Hfr crosses and recombination analysis, a tedious procedure. Hence, an easier process was developed that combined mutation with acquisition of a selectable marker. One way to achieve this is by transposon insertional inactivation, when a gene of interest is disrupted by an antibiotic resistance transposon. To facilitate this approach, suicide vectors carrying antibiotic resistance transposons, natural and artificial, have been

constructed. The transposons chosen are those which insert more or less at random into any DNA sequence in the cell. Popular elements are Tn*5* and Tn*10* and their derivatives. The suicide vector is used to deliver the transposon into the target cell where it survives only by transposing from its carrier replicon into the host cell chromosome (or other viable replicon in the cell).

Transposition events are selected by plating on medium containing the appropriate antibiotic for the resistance gene on the transposon (e.g. kanamycin for Tn*5* and tetracycline for Tn*10*). The survivors are screened for the knockout mutants of interest. Particular mutants are then chosen and genomic DNA from each of these is isolated, digested with a restriction enzyme that does not cut within the marker gene and no more than once within the transposon as a whole, and the fragments are ligated into a suitable cloning vector, e.g. pUC18, to create a gene bank, which is transformed into *E. coli*. Selection of particular transformants can then be for those that have recombinant plasmids carrying the transposon antibiotic resistance gene. This will have been recovered together with some sequences from the gene disrupted. Analysis of several such transposon mutants, where the transposon is inserted at different locations and in different orientations in the gene of interest, will allow the sequence of the intact gene to be determined.

'One of the most popular transposon delivery vectors is the pUT series (de Lorenzo et al. 1990), which have the same *pir* dependent origin of replication and mobilization functions as pEX18 suicide vectors, but carry the Tn*5* transposase gene, and Tn*5* repeat sequences flanking a selectable marker. These vectors have been designed to include many different antibiotic resistance genes, for use in different bacteria, since some are inherently resistant to certain antibiotics.

Fusion vectors

Derivatives of pUT have also been developed that allow the formation of protein fusions, i.e. hybrid proteins. These are constructed for a variety of reasons, including investigation of the cellular location of a particular protein peptide domain, study of transcription and translation control systems, and to facilitate purification of proteins of interest (de Lorenzo et al. 1990). These systems are typified by the *phoA* fusion system. The *E. coli phoA* gene encodes alkaline phosphatase, an enzyme that is easily assayed. Random insertions of the *phoA* gene into a gene of interest, achieved using a modified Tn*5*, can create hybrid genes, where the reading frames of the disrupted gene and that of *phoA* are in register. These hybrid genes produce proteins that have different lengths of the protein of interest at their N-termini fused to PhoA. If the fusion protein is expressed using the transcription and translation signals specific to the protein of interest, then changes in level of expression can be monitored simply by determining alkaline phosphatase activity. This is a powerful tool with which to investigate production of proteins that lack an easily assayable activity. The *phoA* system is used particularly to study production of membrane proteins and their topologies. Alkaline phosphatase is normally secreted into the periplasmic space of *E. coli*, where it is activated. Enzyme protein that remains in the cytoplasm is generally inactive. Accordingly, alkaline phosphatase activity indicates that the PhoA domain of the fusion protein has been transported to the periplasm. In the study of membrane proteins, this technique is useful for mapping the topology of membrane proteins because, when PhoA is fused to a peptide domain that is normally in the cytoplasm then alkaline phosphatase activity remains dormant. In contrast, when it is fused to a peptide domain that is located in the periplasm, alkaline phosphatase activity is revealed (Hoffman and Wright 1985). The activation of alkaline phosphatase reflects the need for protein chaperones, found in the periplasm, to assist the enzyme to achieve active configuration.

One limitation of pUT vectors is that they can only be used in organisms where the transposase gene can be expressed. However, it is now possible to purchase purified transposon delivery vectors, comprising the Tn*5* terminal repeat sequences flanking an antibiotic resistance gene, complexed with transposase enzyme. In the absence of magnesium ions (i.e. in the buffer supplied) the transposase is not active, but upon transformation of the vector/transposase complex into a bacterial cell, where magnesium ions are present, the transposase is activated and transposition occurs (Goryshin et al. 2000). Another potential use of this system is to introduce a gene of interest into the chromosome of a bacterium. This can be particularly important if the gene under investigation is normally located on a chromosome, when gene copy number is essentially one. The suicide vector pMOD carries Tn*5* terminal repeats flanking a multiple cloning site, allowing the insertion any DNA sequence of interest between the repeats and has been provided with the *pir*-dependent replication origin and so replicates only in *pir*+ *E. coli* strains. The recombinant plasmid is isolated and purified and the plasmid DNA is mixed with purified Tn*5* transposase enzyme, and the mixture is electroporated into the recipient bacterium (*pir*$^{-}$), where the novel Tn*5* construct is transposed into the chromosome of the new host. The suicide vector is lost because it fails to replicate.

One problem arising from the use of transposons to mark genes by insertional inactivation is that it is not always straightforward to clone out the transposon marker together with flanking sequences from the new site of insertion, and hence to identify the gene disrupted. To overcome this limitation, the pMOD vector has had the *pir* replication origin relocated and placed between the Tn*5* repeat sequences, beside the MCS (York et al. 1998). Accordingly, not only is an

antibiotic resistance gene transposed but, also, so is a tightly linked silent plasmid origin of replication. Once appropriate Tn insertion mutants have been identified, the chromosomal DNA of these can be purified, digested with an appropriate restriction enzyme, i.e. one that does not cut the transposed sequence, and the fragments can be end-ligated to circularize them. The circles generated are narrow host-range plasmids, that can be recovered on transformation of a *pir*+ *E. coli* strain. This strategy eliminates the need to construct a gene bank in a cloning vector such as pUC18 and provides a ready source of DNA from which to sequence the gene disrupted by the Tn insertion. This is because gene sequences, both promoter proximal and promoter distal to the point of insertion, are recovered simultaneously. If cleavage with one restriction endonuclease fails to recover the gene of interest in its entirety, then another can be tried.

Gene cloning

Foreign DNA is inserted into a plasmid vector by linearizing the circular plasmid molecule with a particular restriction enzyme. The DNA fragment to be cloned – usually generated by the same restriction enzyme used to cut the cloning vector – is joined (ligated) at both ends to the linearized vector to form a circular molecule. The hybrid DNA is then introduced into a suitable bacterial cell by transformation (see Brown 2001; Primrose et al. 2001). The desired recombinant clones then have to be identified. This may be done by selection if the gene of interest confers a selectable phenotype; otherwise, a set of recombinants called a gene bank is collected and the individual members of the set are screened to identify those with the gene of interest.

In contrast to plasmid vectors, which are circular, λ based vectors are linear DNA molecules. In these cases the vector is cut with a restriction enzyme to generate two (insertion vectors) or three (replacement vectors) fragments. If two, the sequence to be cloned (generated with the same restriction enzyme or one that generates compatible single-strand extensions) is inserted between them. This requires the three fragments to be ligated together in the correct order. The desired recombinants can then be recovered by transfecting a suitable cell line of *E. coli* with the recombinant DNA or by in vitro packaging of the recombinant DNA (i.e. generation of reconstituted λ phage particles in the 'test tube') and subsequent infection of a suitable *E. coli* cell line. The latter process is the more efficient and λ packaging kits are commercially available. If a replacement vector is used, restriction enzyme digestion of the vector produces three fragments, of which the two outside fragments are ligated to the fragment to be cloned and the central fragment, often a stuffer sequence (Chauthaiwale et al. 1992), is discarded. Again, the desired recombinants can be recovered by transfection or by in vitro packaging and cell infection (see Primrose et al. (2001) for a more detailed presentation of gene cloning strategies).

Eukaryotic genes are not transcribed in bacteria from their own promoters because these promoters are not recognized by bacterial RNA polymerases. Hence, to express a eukaryotic gene in a bacterial cell it is necessary to join the gene to a suitable bacterial promoter sequence. A number of cloning vectors with cloning sites close to and downstream from active promoters have been developed for this purpose (see Thompson 1988). Many cloning vectors with a bewildering array of properties are now readily available commercially.

A fundamental problem that arises when genes are cloned on a fragment generated by a restriction endonuclease is that what is recovered may not simply be the gene(s) of interest, but also unwanted sequences flanking it. Expression of genes encoded on these additional sequences may complicate subsequent analysis, so it is frequently desirable that these be removed prior to analysis. This can be achieved by subcloning, i.e. the fragment recovered in the primary cloning is cut into smaller pieces using a different restriction enzyme and these, in turn, are recovered in the same or in a different cloning vector. The desired transconjugant is again detected by an appropriate screening process. If the fragment is still considered to be too large, the reducing process is repeated on the smaller fragment with another restriction enzyme until the smallest fragment that still encodes the intact gene(s) is recovered.

An alternative approach that bypasses the problem completely, and which is suitable for small peptides, is to synthesize the gene chemically and then insert it into a suitable cloning vector. This was done in the early days of cloning for the gene for somatostatin – a pituitary hormone of 14 amino acids, the sequence of which was known (Itakura et al. 1977). The genes for human growth hormone, thymosin and insulin have also been synthesized and cloned. A more recent solution to the problem of eliminating unwanted sequences that accompany a gene of interest recovered from a gene bank, because sequencing is now both straightforward and economical, is to sequence the insert and then amplify the gene of interest by PCR. The synthetic fragment can then be cloned into a specialized cloning vector, e.g. pTOPO, and the required recombinant can be recovered in the normal way by transformation of an appropriate cell line (Ramalingam et al. 2004). Such technology allows, in principle, examination of any system, gene by gene.

A second problem, that does not arise with bacterial genes, is encountered with many eukaryotic genes. Not only are they too large to synthesize with existing techniques but, unlike the genes of bacteria, they may also be discontinuous ('split' genes), the continuity of the coding sequence being disrupted by one or more unrelated sequences (introns) (see, for example, Lewin

2000). Such sequences are removed after transcript synthesis but before translation, a process referred to as RNA splicing, i.e. a functional mRNA is produced by splicing together those sequences necessary for the production of the particular peptide. Another approach must therefore be used if the gene is to be recovered and expressed in a bacterial cell. This involves isolating functional mRNA molecules (already processed), which are used as template to synthesize complementary DNA (cDNA) sequences using reverse transcriptase (an enzyme that synthesizes single-stranded DNA from an RNA template). The single-stranded cDNA is then converted to double-stranded DNA and inserted into a suitable cloning vector. The reconstructed, uninterrupted gene is then recovered by transformation of an appropriate bacterial cell line (Primrose et al. 2001). The necessary mRNA can be prepared by one of a number of techniques; which one is chosen depends largely on the task in hand (e.g. White and Radke 1997; Rosenow et al. 2001).

Several mammalian proteins are now being made in bacteria as the result of gene cloning. They include somatostatin, human growth hormone, insulin, several interferons, and tissue plasminogen activator. Many more can be expected in the future.

Genetic engineering is also likely to make a major impact in the field of vaccines. By making only the antigen against which antibody response is required, the risk associated with the intact pathogen is minimized. This technique is being pursued with respect to many pathogens, notably rabies and hepatitis B viruses, malaria, and *Bordetella pertussis* to name but four. The techniques of molecular biology that have been developed are so powerful, both with respect to unlocking the molecular biology of genetic systems and in furnishing the potential to allow specific manipulation of genes, that they offer the promise of major advances in our understanding of many diseases and of better informed positive intervention.

The power of bacterial genetics has also been harnessed to engineer plants to create novel cultivars with desirable characteristics. These genetic manipulations have resulted in the transfer of bacterial antibiotic resistance genes into these plants. Concern has been raised that large-scale cultivation of these new cultivars might exacerbate the spread of antibiotic resistance genes among bacterial pathogens and so hasten the time when antibiotic therapy is no longer effective. However, although it has been shown that bacteria can transfer DNA into plant cells, the reverse process has never been reported, except when artificial transformation systems have been used. Accordingly, while it is impossible to rule out gene transfer from plant to bacteria, it is exceedingly unlikely that it will have a significant impact on the further development of antibiotic resistance in bacteria (Bennett et al. 2004).

Bacteriocins and bacteriophages

MARTIN DAY

Introduction	1	Conclusions	8
Bacteriocins	1	References	9
Bacteriophages	4		

INTRODUCTION

Bacteriocins are a group of proteins secreted by bacteria that kill or inhibit competing strains. Bacteriophages are viruses that infect bacteria. Both agents have antimicrobial activity and they share some features, such as the uptake site on their host bacterium. However, examination of their modes of action, reproduction, and genetics reveals differences. The major difference is that only bacteriophages carry a genome (DNA or RNA) enabling them to reproduce in the cells they infect; bacteriocins are only proteins and cannot reproduce. Irradiating a phage will damage its genome irreparably; thus, an irradiated lysate will have no killing activity. Bacteriocins have no genome and thus are insensitive to this level of irradiation and retain their activity fully. Both bacteriocins and phages can kill susceptible cells.

Bacteriocins have for decades been utilized as food additives to limit spoilage. The continued demand for a longer shelf-life of food and other biologically degradable products has meant that these desirable properties of these bioactive agents have been more seriously investigated in recent years when research has shown phages of lactobacilli are a serious problem for the dairy industry. They have been used in the medical arena for phage typing of pathogens such as *Staphylococcus* spp. and as antibacterials. Some are also widely used as recombinant DNA vectors as cloning and expression vectors.

BACTERIOCINS

Microorganisms naturally produce a range of protein components from simple polypeptides to very complex macromolecules, such as antibiotics, toxins, pili, adhesins, siderophores, flagella, etc. Many of these form part of an array that forms a defense system. Bacteriocins are grouped under the term 'toxins' and provide a means of defense against, or a growth advantage over, other microorganisms in the same ecological niche. The term 'colicin' is used to describe those antagonistic compounds produced by *Escherichia coli* (Frederique 1957). The term 'colicin' was coined by Gratia and Frederique (1946) to describe these substances, the effects of which had been observed by Gratia (1925). Jacob and Woolman (1953) introduced the general term 'bacteriocin' to describe substances with similar activity produced by a wide range of bacteria. Tagg et al. (1976) defined bacteriocins, a subgroup of bacterial toxins, as proteinaceous compounds that kill closely related bacteria. Although this is true for most bacteriocins, it is evident that these molecules take many forms and may have bactericidal actions beyond closely related species. Individual bacteriocins are named by attaching 'cin' to the root of the genus or species name. For example, *Pseudomonas aeruginosa* produces aeruginocins and *Bacillus megaterium* produces megacins. The synthesis of most colicins (and this will probably be true of bacteriocins in general) are SOS-inducible (Pugsley 1984a,b). Frequently bacterial species carry genes that encode both the production of one or more bacteriocins and immunity to them on the chromosome or on plasmids (Frank 1994). The significance of the latter location is that the distribution of individual plasmid types in bacterial communities fluctuates under selection, for and against the plasmid and host cell, which provides opportunities for closely related and competing populations to

gain and lose advantage. Loss and acquisition of bacteriocins is a consequence of plasmid stability, incompatibility and transfer. Thus, a great diversity of bacteriocins can be produced within a single species. Bacteriocins have a spectrum of sizes; generally proteinaceous agents, they are sometimes complexed with lipids, carbohydrates, or other distinctive proteins (Lewus et al. 1991; Nissen-Meyer et al. 1992; Jiminez-Diaz and Rios-Sanchez 1993). There are three general classes:

1. microcins, small molecules produced in stationary phase by gram-negative bacteria
2. lantibiotics, small molecules produced by gram-positive bacteria
3. bacteriocins, a group encompassing medium to large phage-like structures, whose synthesis generally appears to be induced by the SOS response.

It has been shown that bacteriocin synthesis provides the strain with a growth advantage over isogenic nonproducing strains (Ruiz-Barba et al. 1994). Since producing these antimicrobials is an energy-costly process, the benefits to the producer must be due to selective pressure. The energy cost must be less than the energy benefit resulting from their synthesis. Viewed in this light their synthesis should be well regulated and expression directed to times when it will be of benefit. Thus, bacteriocin synthesis reflects this by being sensitive to pH, temperature, medium composition, SOS response induction, etc.

These proteins share many characteristics. Many have a low molecular weight, are cationic, are amphiphilic, tend to aggregate, and are benign to the producing organism. They kill sensitive cells in distinct ways, targeting the cell membrane (e.g. phospholipases), affecting DNA tertiary structure (DNA gyrase), or affecting DNA/RNA integrity (ribonuclease or deoxyribonuclease activity). Since their sites of synthesis and modes of action are frequently intracellular, they must also be able to enter susceptible cells to exert their effects. Many are capable of killing activity at extremely low concentrations (one to a few molecules per susceptible cell) and target specific cellular pathways. Death of the cell is a consequence of transport collapse at membrane level, depleting proton-motive force (pmf) and resulting in a rapid reduction in indispensable metabolites or ions, or blocking of macromolecule synthesis (protein or DNA). Thus, due to the specificity of the target, the effect on cell metabolism is catastrophic. There is a further and historical complication in this analysis, as bacteriocins are effectively antibiotics, so there is an activity of structural and biochemical overlap between these molecules. Historically, some were initially regarded as antibiotics and have now been recognized as bacteriocins, and vice versa for others. Thus, their diversity in types and modes of action provides an indication that these molecules have great significance for microbial populations and the dynamics of interactions of these within communities. Bacteriocins are probably present in all bacterial species, and within each species there are probably hundreds of different kinds (Riley and Gordon 1992). For example eubacteria (*E. coli*), the archae (*Halobacteria* Torreblanca et al. 1994), and *Streptomycetes* all commonly produce broad-spectrum antimicrobials (Saadoun et al. 1999). Microbes invest considerable energy in their synthesis. What is less clear is how this diversity arose and what roles these agents serve in microbial communities.

Assay

A simple method for assaying bacteriocin activity is to take the supernate of an overnight culture of the putative bacteriocinogenic strain grown in broth culture, dilute this as a series of doubling dilutions, and place 10-μl drops on the surface of a dry nutrient agar plate prespread with a lawn of the indicator bacterium. After overnight incubation the lawn will have grown and the area containing bacteriocin will show a circular zone of clearing. The further down the dilution series the inhibition zones are found, the more bacteriocin is produced by the strain (Benkerroum et al. 1993). This demonstration of the inhibitory effect is also the basis of bacteriocin typing methods.

Modes of action

A neat and satisfying taxonomy of bacteriocins remains to evolve but may come through an interrogation of bacteriocin sequences. Bacteriocins have been described variously in terms of size, types of activity, and chemical nature. As there is no consistent theme it is difficult to obtain a proper grasp of their relationships. It seems sensible to categorize them through their modes of action, but the problem with this approach is that for most, the mechanisms of activity are unknown. However, the general strategies employed by these antimicrobial agents are illustrated by the examples that follow.

DESTRUCTION OF MEMBRANE POTENTIAL

The membrane is composed of many different molecules in complex functional associations. Bacteriocins that target individual proteins, in associations concerned with membrane potential, lead directly to a loss in pmf. Bacteriocins produced by lactic acid bacteria commonly act by this mechanism, but the role of receptor proteins and the mechanism by which pmf is depleted remain unresolved. Many that act in this way are lantibiotics and are produced only by gram-positive bacteria. The most striking feature of lantibiotics is the occurrence of intramolecular rings, introduced by the thioether amino acids lanthionine and 3-methyllanthionine, and unusual

amino acids such as didehydroalanine and didehydrobutyrine (Bierbaum and Sahl 1993). These smaller bioactive molecules, which in gram-positive strains are 30–60 amino acids in size (Jack et al. 1995), as a group have both broad and narrow spectra of activity. Some are phospholipases that cause susceptible cells to leak intracellular contents through the damaged cell membranes (Kim 1993). In gram-negative bacteria some of the colicins destroy the membrane potential by forming pores in the membrane (Lau et al. 1992). Colicin A is an example of a water-soluble protein that inserts into lipid bilayers and produces this effect (Lakey et al. 1992, 1994).

NUCLEOLYTIC AND RELATED ACTIVITIES

Sano et al. (1993) examined pyocins S1 and S2, S-type bacteriocins of *P. aeruginosa* that have different receptor recognition specificities. The sequence homology suggests that pyocins S1 and S2 originated from a common ancestor of the E2 group colicins. Purified pyocins S1 and S2 make up a complex of the two proteins. Both pyocins cause breakdown of chromosomal DNA, as does colicin E2, as it has endonucleolytic activity (Lau et al. 1992). Colicin E3 has RNAse activity, cleaving the 16S RNA moiety of the 30S ribosome subunit. Microcin B17 inhibits DNA gyrase (Vizan et al. 1991).

INHIBITION OF PROTEIN SYNTHESIS

The large particulate bacteriocins, e.g. the pyocin-R (aeruginocins) produced by *P. aeruginosa* (Hayashi et al. 1994), are derived from defective phage particles; they contain the phage component capable of attaching to the cell surface. This class of agent generally shows a narrow spectrum of specificity, inhibits protein synthesis, but does not lyse the cell. The genes specifying this type of bacteriocin are encoded chromosomally.

Synthesis

The physiological state of the cell affects all cellular metabolism. The biosynthesis of bacteriocins is no exception and thus the yields of bacteriocin depend on local environmental influences on the producer cell physiology and the regulatory mechanisms governing the expression of the bacteriocin. For example, Malkhosyan et al. (1991) showed that levels of DNA supercoiling are influenced by anaerobic metabolism and that this regulates the level of expression of the colicin genes. The expression of the *cea* gene, which encodes colicin El, on the ColE1 plasmid was greatly increased when the cells were grown anaerobically (Eraso and Weinstock 1992). By using *cea–lacZ* fusions to quantitate expression, levels of β-galactosidase produced under aerobic conditions from the fusion were found to be only a few percent of the anaerobic levels. The gene is also induced by the SOS response and subject to catabolite repression.

The majority of bacteriocins, such as colicins, aeruginocins, megacins, etc., are produced as the result of normal gene expression. Their synthesis starts with gene transcription, producing an mRNA, which is then translated into an active protein. This synthetic sequence is mediated by ribosomes (Pugsley 1984a, b). The lantibiotics class of bacteriocins (Hansen 1993) frequently contains unusual amino acids that contribute to their properties and functions. Most are synthesized as peptides by nonribosomal mechanisms (Klienkauf and von Dohren 1990), but some are synthesized by pathways that involve post-translational modification of ribosomally synthesized precursor peptides. Examples of the latter are nicin and subtilisin (Nishio et al. 1983).

RELEASE FROM CELLS

The microcins, e.g. colV, are small (6 kDa) and are not induced by the SOS system; their release coincides with the stationary phase. They do not utilize a lysis protein for release but have a dedicated pathway (Gilson et al. 1990; Van der Wal et al. 1995). The lantibiotics generally use a dedicated secretion pathway (Fath and Kolter 1993).

UPTAKE SITES

It has long been recognized that only a few molecules (perhaps only one) are necessary to kill a susceptible cell, and the receptor targets are known for several bacteriocins, in particular some of the colicins. Susceptible cells bear specific protein receptors in their outer membranes, which explains why colicins attach only to certain strains of bacteria.

'Tolerance' and 'resistance' are two terms that are often incorrectly and synonymously used in medical microbiology. The term 'tolerance' describes a state in which the bacteriocin fails to gain access to the sensitive target site within the cell because the receptor is absent or altered so the colicin remains unattached to the cell; thus, it cannot exert a lethal effect. Thus, tolerance may be produced by mutations (e.g. of *tolA*, *tolB*, or *tolC* genes) that affect the outermembrane proteins and the interactions between the cytoplasmic and outer membranes, which prevent the uptake of the bacteriocin into the cell. Resistance occurs when the bacteriocin can be taken up but, because the site is lost or altered by mutation, the cell remains unaffected. There is often a commonality in receptors, which also have a cellular functional role, utilized by phage and bacteriocins. For example, the site used by colicin κ and bacteriophage T6 is implicated in nucleoside uptake. The colicins E1, E2, and E3, and phage BF2 (phage T5-like) use a glycoprotein receptor involved in vitamin B12 uptake. TonB is a membrane-transport protein utilized by many substances and *tonB*- membrane mutants are tolerant to colV

(Pugsley and Schwartz 1985). This commonality signifies that overlap between resistance to inhibitory molecules can be shown.

Host range

Although the general statement that most bacteriocins have a narrow host range (Jack et al. 1995) is true for many, work on bacteriocins produced by *B. megaterium* (megacins), for example, shows that some have a broad spectrum and attack most strains of this species. These megacins are phospholipases and cause susceptible cells to leak intracellular contents by attacking the membrane phospholipids. The bacteriocins produced by lactic acid bacteria exhibit a relatively broad antimicrobial spectrum and are active against several food-spoilage and health-threatening microorganisms (Kim 1993).

Immunity

The production of bacteriocins is the result of deregulation of one or more genes and, in many instances, the release is by a dedicated export mechanism and not cell lysis (Lakey et al. 1994). Strains harboring plasmid or chromosomally encoded colicins, e.g. colicin E3, have immunity to the lethal activity of the colicin (Riley 1993; Frank 1994).

Clinical, technological, and ecological importance

Applications of bacteriocinogeny have been used as epidemiological tools through bacteriocin typing of clinical strains to aid in the identification or discrimination of opportunist and pathogenic bacterial strains. Bacteriocins that show narrow specificity within individual species or genera, such as the bacteriocins of gram-negative bacilli, have been particularly useful in bacteriocin typing. A strain may be characterized actively by the range of activity of its bacteriocins against a set of indicator strains of the same or closely related species, or passively in which it is characterized by the pattern of its susceptibility to the bacteriocins of a set of indicator strains. The former approach has proved particularly useful in typing isolates of *Shigella sonnei* (see chapter 53, *Shigella*) and *P. aeruginosa* (see chapters 62, Pseudomonas; and 63, Burkholderia spp. and related genera), and a combination of the two approaches has been used for *Proteus* spp. (see chapter 55, *Proteus*, *Morganella* and *Providencia*). In colicin and pyocin typing, strains to be typed are streaked across an agar plate and grown overnight so that their bacteriocins diffuse into the agar. Growth is removed from the surface and remaining viable bacteria are killed by exposure to chloroform, and then the indicator strains are streaked across the original line of growth and again incubated overnight. The bacteriocin type is indicated by the pattern of inhibition of the indicator strains (Gillis 1964).

Bacteriocins have been used in the food industry for a long time. There is a potential for this to increase as more food is required to have a longer shelf-life. Applications stem from their lack of mammalian toxicity and the spectrum of activities available. For example, bacteriocins produced by lactic acid bacteria exhibit a relatively broad antimicrobial spectrum and are active against several food-spoilage and health-threatening microorganisms (Kim 1993) and some produce bacteriocins active against *Listeria monocytogenes*, a food-borne pathogen (Hechard et al. 1993). Nicin, produced by some strains of *Lactococcus lactis subsp. lactis*, was originally described in 1928 and is the most highly characterized bacteriocin produced by lactic acid bacteria. Nicin has been permitted as a food additive in the UK since the early 1960s and is currently an accepted food additive in at least 45 other countries (Harris et al. 1992). One example of its use is in the preservation of liquid egg (Delvesbroughton et al. 1992).

The activity or role of colicins in vivo is not clear. Pugsley (1984a) suggested that high proteolytic activity in the intestinal tract (an anaerobic environment) would degrade colicins and thus lead to an effective loss of their activity. Later Luria and Suit (1987) stated that 'colicinogeny appears an unnecessary complication in the life of coliform bacteria.' It seems a little premature to write off a group of proteins that are expressed from highly organized genetic systems and that selectively target specific pathways in selected species. It appears more likely that they do have an ecological role to promote the growth of the producer against its immediate competitors. These are likely to be strains with a similar metabolism (biochemistry and physiology), and will be related strains and species. As the particular and immediate requirement for bacteriocin activity is to inhibit cells adjacent to the one producing the bacteriocin, it is local spatial activity that is required. An agent that diffuses into larger volumes will help other competitors. This argument is supported by Frank (1994), whose hypothesis was that bacteriocin diversity in species could not occur if the organisms mixed freely. Spatial variation and poor habitats favored both susceptibility and bacteriocin diversity in strains. Bacteriocin producers are favored in good habitats where competition is likely to be high.

BACTERIOPHAGES

Bacteriophages (phages) are viruses that grow in bacterial cells utilizing their biosynthetic systems for reproduction. Their effects were first observed by Twort (1915), who described an infectious agent that distorted the morphology of staphylococcal colonies. D'Herelle (1917) found a filterable agent that sterilized broth cultures of *Shigella* spp., and he believed such agents

might be useful in combating bacterial diseases, as they had no infectivity towards eukaryotic cells. More information about the history and current status of phage therapy can be obtained from a review by Summers (2001).

Phages are extremely common in the environment and can be found wherever their host bacteria are present. They are readily detected for most bacterial species. It is probable that all bacteria are sensitive to one or more phages which thus prey on their specific host strain or strains; it is rare to find one that infects a large number of species. The population density of their host cells is a major component determining the density and distribution of phage (Ogunseitan et al. 1990; Proctor and Fuhrman 1990). For example, high counts of phage occur in biofilms ($>10^8$/cm) (Ewert and Paynter 1980) where bacterial density is high, but are far lower in bulk waters ($10^{3–4}$ cfu/ml) (Saye and Miller 1989) where bacterial density is also low. In sewage, enumeration by electron microscopy (Ewert and Paynter 1980) revealed $10^{8–10}$ phages/ml, compared with about 10^8/ml in freshwater and the open ocean (Bergh et al. 1989). Direct counts of bacteriophage in soil are also high, some 4 percent of the total bacterial counts (Ashelford et al. 2003).

Phage morphology

Examined as a group, phages show considerable morphological diversity (Ackermann 1983; www.virology.net/Big_Virology/BVHomePage.html). Some are filamentous, isometric, and superficially resemble animal viruses, whereas others show complex morphologies. The capsid or the phage head is the structure containing the genome; this can be single- or double-stranded DNA or RNA. Some phages are virulent, killing each cell they infect, whereas others are temperate. In the latter case, the phage resides, as a prophage, in a cell termed a lysogen and replicates synchronously with the cell. When phage replication is completed the particles are released from the cell. They usually contain a phage genome. The phage capsid recognizes an adsorption site on the outside of a susceptible cell, binds to it, and injects the genome, held within the capsid, into the cell. The genome then redirects the cellular metabolism to synthesize more phage. In the lysogenic state, the phage genome does not disrupt bacterial metabolism and replication but may contribute specific characteristics to its host, e.g. toxin production by *Corynebacterium diphtheriae* (see chapter 39, Corynebacteria and rare coryneforms) and *Streptococcus pyogenes* (see chapter 33, Streptococcus and lactobacillus).

Single-stranded RNA phages

These are the simplest of phages in terms of their genomic size and morphology. This is not to imply that the organization of their replicative cycle or their economy in genome size, relative to other phages, makes their biological activities simple, but it reflects an evolutionary adaptation. They rely on the host cell for all metabolic activities except for certain replicative functions to complete their life cycle. The RNA coliphage MS2 (*Leviviridae*), termed male-specific, utilizes the pilus of an F^+ *E. coli* cell as an infection site. The MS2 capsid is icosohedral, largely composed of a single protein species, which encloses a phage genome of 3 569 nucleotides (nt) of linear plus strand (sense) RNA. The capsid binds to the side of the F pilus and the phage genome is transferred into the cell. Once internalized, the phage RNA genome acts as messenger RNA and is translated by the ribosomes. There is no transcriptional control, as promoters and RNA polymerase are not involved, and yet there is temporal control over the expression of proteins. This is achieved by changes in conformation of the RNA genome. Relatively large numbers of coat protein molecules (van Duin 1988) are needed per virion. The RNA-directed RNA polymerase, a lysin gene, and an absorption protein are synthesized in smaller amounts and their expression is regulated by secondary structures formed in the phage genome (Kastelein et al. 1982; Berkhout et al. 1987).

On average, 200 phage particles are produced from one cell infected by one phage and this can be achieved in as little as 22 minutes. To achieve this efficiency, replication proceeds alongside expression and the phage polymerase acts in concert with some host accessory functions. The polymerase initiates repeatedly, at the 3′ end of the RNA (Haruna and Spiegelman 1965), enabling multiple copies (of the minus strand) to be made. Concurrently these full-length minus strands are then copied to yield the plus strands, which are used initially for the expression of phage proteins. Later in the infection cycle the plus strands are individually packaged into a capsid. Cell lysis is induced by the final product, the lysis protein.

Single-stranded DNA phages

The tailless icosoheral phage ϕX174 (*Microviridae*) was the first single-stranded DNA phage to be identified (Hayashi et al. 1988). It has a circular genome (5.4 kb) that codes for ten proteins. Four different monomers are present in the capsid, one of which is an internal protein and is surrounded by a second (60 copies), which forms the icosahedral capsid. The other two monomers form ‘spike’ proteins, which are essential for infectivity. The phage receptor is a lipopolysaccharide that allows entry of the phage genome. This DNA is used as a template for single minus-strand synthesis and is entirely dependent upon the host cell to create a biologically active phage genome (Goulian et al. 1967). Once established as a duplex, the phage genome reproduces by rolling circle

replication (Lewin 1987). This is initiated by a phage replication enzyme expressed from the newly formed duplex. Transcription proceeds in the same direction as replication. As the pools of capsid precursors and replicated genomes increase, the plus strands become encapsulated (Aoyama and Hayashi 1986). The reproductive cycle can be complete within 13 minutes, resulting in cell lysis yielding up to 180 phage particles

Although the replication cycles of the filamentous phages are similar to that of ϕX174, their structure, attachment, and the absence of cell lysis on phage release are different (Lindquist et al. 1993). The genome of phage M13 (*Inoviridae*) is circular (6407 nt) and encapsulated as a single strand by a flexible helical capsid composed largely of a single protein species (Model and Russell 1988). At the ends of this tube-like filamentous phage capsid are the 'minor' proteins. Those at one end are responsible for phage attachment to the F plasmid pilus via which the phage genome becomes internalized. Replication proceeds in the same manner as for ϕX174. The host cell continues to grow and divide and as the phage particles become 'mature' they are released through an intact cell envelope. Thus, phages are continually released after a latent period of 30 minutes, resulting in very high phage yields. The filamentous phages are good cloning vectors because foreign DNA can be spliced into the genome at appropriate sites and transformed into a host bacterial cell to give high yields of cloned material. The splicing of novel genes with the coat protein gives protein chimeras in which the novel peptide component may be exposed on the capsid surface (Barbas et al. 1991). As methods for purifying phages are well established, this provides an easy method for screening for protein activities.

Double-stranded DNA phages

The double-stranded DNA phages are divided into two groups, based on their virulent or temperate nature. Phage T4 (*Myoviridae*) is a virulent and morphologically complex phage; it has an elongated icosahedral capsid composed of one major and several minor (in terms of percentage) proteins (Mathews et al. 1983). The capsid is placed upon a tail comprising a core and contractile sheath on a base plate with six kinked tail fibres. In the capsid the 170-kb DNA genome is linear and double-stranded, with about a 5-kb terminal repeat. Free phage particles recognize a lipopolysaccharide receptor on the cell surface and become anchored to it. The proteins in the baseplate then reorientate to allow the core to be driven onto and through the cell surface as the sheath contracts. The DNA is then extruded from the head into the cell's cytoplasm. Phage replication uses the host polymerase and normal vegetative σ factor (σ_{70}). The phage reproductive cycle, from infection to lysis, is highly organized and complex. For example, transcription is temporally organized such that some genes are expressed early and in the middle of the replicative cycle (Mosig and Eiserling 1988). The late genes are transcribed by a phage-encoded σ factor and also govern DNA synthesis. Immediately after infection this phage degrades the host genome and inhibits host transcription. After replication, the concatomeric DNA is injected into the preformed heads and cut, and then the tail structures are added (Bhattacharyya and Rao 1993). Expression of the late phage genes results in cell lysis and release of ⩾200 mature phage particles 23 minutes after infection. The phage λ (*Siphoviridae*; 48.5 kb) has an icosohedral capsid and is termed a temperate phage. It interacts differently to phage T4 with its host. When carried by the host (λ replicates in-step with the host) it is termed a 'prophage' and the cell is termed a 'lysogen'. Phage replication and consequent cell lysis require phage replication to be induced. This is generally promoted by the SOS response (Ptashne and Gann 2001).

Experimental analysis

Phages may be investigated by a variety of molecular and standard laboratory techniques. Three terms describe key points in the analysis of phages. A plaque-forming unit (pfu) is a phage particle that is capable of forming a plaque. The efficiency of plating (EOP) is the proportion of pfu to total phage particles (enumerated by electron microscopy) in a lysate (Adams 1959). Finally, the multiplicity of infection (MOI) is the ratio of host cells to phage in a mixture.

ASSAY

It is a simple procedure to estimate the number of phage particles in a lysate. As titers are frequently 10^6–10^{11} pfu/ml, 10-fold dilution series of phage lysate is prepared to obtain 10–100 pfu/ml. A small volume (e.g. 100 μl) of diluted lysate is mixed with an equal volume of host bacterial cells in about 3.0 ml of 0.6 percent molten nutrient agar, held at 46°C. This is vortex-mixed and poured on to the surface of a standard nutrient agar plate. After overnight incubation, to allow the plaques to develop in the growing bacterial lawn, the number of plaques formed will reflect the original phage concentration and the dilution of the lysate. Thus, at high dilutions, no phage will be present and no plaques will develop. At a lower dilution, a few plaques (zones of lysis a few millimeter in diameter) will be present in the lawn, and at the next dilution, the plaque count will be high and the plaques may even merge in places. At the next dilution, the MOI will be about 1:1 and confluent lysis will occur, although it is likely that a few bacterial colonies, resistant to the phage, will grow (at a frequency of 10^{-8}). This may be due to phenotypic variation (the lack of expression of a phage uptake site) or to a resistant mutation (leading to a loss of the target

site), or the cell may become infected by a normally lytic phage and yet become lysogenized. In each case, the cell remains unaffected by the phage and continues to grow. The titer of phage is calculated by dividing the dilution assayed into the plaque count from the plate by the highest number of countable plaques.

PLAQUE MORPHOLOGY

Phages can replicate only in an actively metabolizing host cell. A poor nutritional environment will reduce the plaque size and probably also reduce the phage yield. The morphology of the plaque is due to repeated cycles of infection, replication, and lysis of the phage; from the point of infection of a single cell, phages released by lysis infect adjacent cells. This process repeats itself while the bacteria in the lawn are growing, causing a circular plaque to form. Thus, the titer and plaque morphology remain consistent provided the media, incubation conditions, and host are constant. Changes in environmental conditions and the genetic status of the host bacterium or the phage can all influence both plaque morphology and the reproductive success of the phage. For example, virulent phage can display 'a temperate' nature when their host is growing slowly (Ripp and Miller 1998).

TRANSDUCTION

Transduction is achievable by only some phages. For gene transfer to occur, a proportion of the phage particles generated in a lysate have to package some host chromosomal DNA instead of a phage genome. The phage particle acts as a vector for host chromosomal genes, transferring the packaged sequence into the cytoplasm of a recipient cell. Providing the DNA sequence has homology with a recipient sequence (chromosomal or plasmid), recombination can then occur. This is mediated by the host-specified RecA protein, enabling replacement of the host sequence by integration of the transferred sequence. The process is termed transduction. If any gene on the bacterial chromosome may be transferred by the phage, this is termed generalized transduction (Margolin 1987), but if the phage will transfer only a few genes from one site on the genome, this is termed specialized or restricted transduction (Weisberg 1987).

About 2 percent of the phage particles produced by the *Salmonella typhimurium* phage P22 contain host DNA (Ebel-Tsipis et al. 1972), as do about 0.3 percent of *E. coli* phage P1 in a lysate (Lennox 1955). The frequencies of transfer of auxotrophic markers varies between 10^{-5} and 10^{-7} per pfu (Harriman 1971) for both of these phages. However, Schmeiger (1972) has shown that with different genes and hosts the frequencies can vary over 1000-fold.

There are various fates for DNA transduced into a recipient cell. The DNA that is recombined is stably inherited, giving rise to a stable transductant. The displaced strand is degraded and the nucleotides are reutilized. If the DNA sequence fails to become integrated, then it may persist for several generations, producing what is termed 'abortive transductants' (Ozeki 1959). These transductants show unilinear inheritance of the character transferred. This is explained by using a recipient cell that is an auxotroph (carries a mutation in the gene coding for an enzyme required for the synthesis of an amino acid), so it cannot synthesize a particular amino acid. This is transduced to prototrophy by an 'abortive fragment' that contains the prototrophic gene so the cell is able to synthesize the amino acid. When the cell divides, one daughter inherits the wild-type gene and continues to express the enzyme and consequently synthesizes the amino acid and grows. The other cell now has the mutant genotype but is phenotypically wild-type; it retains an active biosynthetic pathway while the enzyme retains its activity. This is lost gradually as it becomes diluted out through growth and cell division; the cell grows, but increasingly slowly. Hence, abortive transductants generate very small colonies, which appear some time after the wild-type has fully grown. The condition is relatively stable as less than 1 percent of cells go on to become complete transductants (Ozeki and Ikeda 1968). Schmeiger (1982) has shown that abortive transduction by P22 is a common phenomenon and varies over a range from 50 percent to less than 1 percent for different loci.

Specialized transduction occurs with *E. coli* phage λ. In this type of transduction the phage enters the chromosome by site-specific recombination at *attB*, using a homologous sequence on the phage termed *attP* (Weisberg and Landy 1983), to form a lysogen. Transducing particles are formed by the illegitimate excision of the phage genome, in which part of the phage sequence remains in the chromosome to be replaced by an adjacent host chromosomal sequence. Thus, genes to one side or the other of the *attB* site may be packaged in the capsid (hence the term specialized). The transducing phage genome is defective and cannot reproduce in the recipient cell. These transducing phages occur at a frequency of about 10^{-6}. If these defective phages coinfect a new recipient with a wild-type phage, 50 percent of the phage in the lysate produced from that cell will be capable of transducing the host gene. The frequency of transduction now is far greater; it can be 100 percent (Lewin 1987). Transducing phages of both types are common in other genera.

ENVIRONMENTAL ROLE

The role of phages in natural bacterial populations remains largely a point of conjecture. They seem to have a dramatic influence on population densities of bacteria in natural habitats (Ogunseitan et al. 1990; Proctor and Fuhrman 1990). Interactions between bacteriophages and planktonic bacteria in aquatic environments have

shown that the abundance of free viruses can exceed that of planktonic bacteria by over an order of magnitude (Bergh et al. 1989). Short-term dynamics imply that bacteriophages can contribute to the control bacterial growth in situ (Bratbak et al. 1990). Transmission electron microscopic (TEM) studies indicate that 1 to 5 percent of planktonic bacteria were visibly infected by phage (Proctor and Fuhrman 1990). Bacterial mortality due to phage reproduction suggests phages can, at times, be entirely responsible for bacterial mortality (Bratbak et al. 1990; Proctor and Fuhrman 1990). Thus, it seems that phages can be significant moderators of microbial populations in a variety of natural environments (Ashelford et al. 2003). These include those in animal and plant as well as populations in water bodies and soil, and between bacterial growth, phage production, and chlorophyll (Cochlan et al. 1993).

Host range has been established by the observation of plaques on putative host strains and on this basis most phages have a narrow host range. There is a widespread assumption that the plating range (i.e. the ability of the phage to form plaques) is a direct reflection of the transduction range. The ambiguity of this has been illustrated with *E. coli* phage P1. Productive infections with phage P1 can be made from *Citrobacter freundii*, *Shigella* spp., *Salmonella* spp., Serratia spp., *Enterobacter liquefaciens*, *Erwinia* spp., *Proteus* spp., *Pseudomonas* spp., and *Klebsiella* spp. (Yarmolinsky and Sternberg 1988). In addition, phage P1 can naturally transduce DNA into *Yersina* spp., *Flavobacterium* sp. M46, *Agrobacterium tumefaciens*, *Alcaligenes faecalis*, and *Myxococcus xanthus*. Goldberg et al. (1974) have reported transduction by phage P1 into *S. typhimurium* even though they were unable to isolate stable lysogens and *Enterobacter amylovora* lysogens did not produce P1 phage. This provides evidence to support the proposal that the transduction and titration ranges for a phage are not unambiguously equivalent and the associations between phage and their host bacteria are not clear-cut. Thus, the contribution of phages to gene exchange remains an open and unanswered question. In addition, the host range can be influenced by the presence or absence of adsorption sites and the mechanism of phage replication. The restriction enzymes possessed by the new host target the phage genome (Roberts 1985). If the phage fortuitously evades the restriction enzymes and becomes modified, to shield the restriction sites, or if these sites are absent, then the phage may be able to replicate.

PHAGE IDENTIFICATION AND TYPING

The specificity and variety of phages that can infect bacterial species have enabled phages to be used for the identification of a species. Strain typing by determining phage sensitivity patterns within a species can be achieved when various phages will attack only a proportion of strains. Phages that lyse all members of a particular species have been used in the identification of *Brucella abortus* and *Bacillus anthracis*. The phages active on *Vibrio cholerae* are specific in their action on serotypes or biotypes. Phage typing within species has been most widely developed and most effectively used in the epidemiological investigation of *Staphylococcus aureus* infection and for strain identification within several *Salmonella* serotypes, including typhi. Typing phages are propagated on a susceptible host strain of the test species to give a high-titer phage suspension, which is then diluted to a concentration (the routine test dilution (RTD)), which gives barely confluent lysis of the propagating culture growing on a solid medium. In phage typing, a set of phages active on only some strains within a species is applied to a lawn of the isolate in question on an agar medium. After incubation, susceptibility is seen as lysis (i.e. plaques) produced by particular phages. The pattern of activity gives the phage type of the organism (Parker 1972).

CONCLUSIONS

Both bacteriocins and bacteriophages are universally present in microbial populations, affecting growth and biochemical relationships within and between bacterial populations (Ashelford et al. 2000). This relationship now clearly extends to interactions, like the pathogenicity endowing genotypes, with higher organisms. Frank (1994) has suggested that the great diversity of bacteriocins produced by a single species cannot occur if the organisms mix freely. His analysis suggests that spatial variation and poor habitats favor susceptible and polymorphic strains, populations with a variety of bacteriocin types. Toxin producers are favored in good habitats since the rate of competition for resources is lower. Although most bacteriocins inhibit the growth of closely related bacteria, some, typified by those produced by lactic acid bacteria, exhibit a relatively broad antimicrobial spectrum and are active against several food-spoilage and health-threatening microorganisms. Thus, there is circumstantial evidence for a role in the regulation of competing bacteria.

The most general use of bacteriophages in the medical sphere has been to phage type bacterial strains of clinical importance. They have been studied since the 1940s and have provided basic information on how DNA and RNA genomes replicate and express genes (Boyd and Brüssow 2002). Because of the relative ease with which they can be grown, purified, and now manipulated, they have become of primary importance (with plasmids) in the development of the molecular biological techniques used to clone and analyze genes and their products. Thus, they have provided a basis for the development of the biotechnological era.

Those debating the risks of recombinant genes being transferred from genetically manipulated bacteria into indigenous bacterial populations now accept that

transfer will occur. Although bacteriophages may be one class of the mediators of such gene exchange, it is still an open question as to how efficient they might be as mechanisms for exchange in situ or in vivo. It will be an interesting step in our ecological appreciation of these genetic determinants when their true ecological value to microbial populations can be demonstrated.

Evolution of pathogens within their host	28	References	34

INTRODUCTION

Infection is a complex and dynamic interaction, the outcome of which determines the onset or avoidance of disease. The term 'pathogen' denotes a microorganism that is able to cause disease in an animal, fish, plant, or insect host, while 'pathogenicity' or 'virulence' is the ability of that microorganism to induce disease in one or more target hosts. Virulence can be defined as the capacity of bacteria to cause disease; virulence determinants are those bacterial products or strategies that contribute to virulence, i.e. those cell-surface-associated or extracellular factors that promote tissue colonization or invasion, protect the bacterial cells from innate host immune defenses, and damage the host. While the expression of such virulence determinants is tightly regulated, they are not usually essential for bacterial viability or growth in vitro. The interplay between host- and pathogen-derived factors will determine the final outcome of an infection, which will depend on the relative degree of susceptibility or resistance of the host as well as the intrinsic virulence of the pathogen.

All living organisms are programmed with a biological capability to survive, replicate, and spread. From an evolutionary perspective, genetic modifications that improve any of these attributes will be selected for and these ultimately lead to the enrichment of such organisms within a given environmental niche. For pathogenic microbes, many of which have become highly adapted to a specific host, the death of the host is not necessarily an indicator of pathogen success. This is because it signals the destruction of an environment that has provided nutrition and protection. Pathogenic microorganisms cannot be considered as 'malicious' since they do not 'deliberately' cause disease or the subsequent death of a host. Pathogenic bacteria are unicellular microorganisms that can ensure the survival of some of their number by infecting other hosts. If, during the process of infection, the host dies, pathogen survival will depend on transmission to a new host, a process that may depend on its capacity to survive in diverse environments. The manifestation of disease is very much symptomatic of the exploitation of host resources by the pathogen for promoting bacterial survival, replication, and dissemination. Thus, the lifestyle of pathogenic bacteria revolves around: (1) locating a host; (2) finding a replication niche; (3) initiating an infection; (4) progressing the infection; and (5) dispersal to a new host. For a bacterium to progress from one stage to the next, variations in sensory inputs that signal environmental change must be perceived and acted upon, for example by the induction of gene expression. New environmental signals may derive from movement from one environment to another, may be due to the actions of bacteria within a given environment, or may be a consequence of host responses to the activity of the bacteria. Thus, from a prokaryotic perspective, the successful interaction of bacterial cells with mammalian host tissues depends on a

coordinated response not only to environmental cues such as nutrient availability, bacterial cell population density, temperature, osmolarity, and pH, but also to diverse host cell effector molecules. For example, bacterial pathogens secrete toxins that either release the nutrients from host tissues or alter the host internal environment to optimize bacterial growth and dissemination. The host responds to these changes by attempting to rectify the physiological and biochemical imbalances induced by the pathogen. Together, the damage caused by the pathogen and the processes elicited by the host during infection are manifested as disease.

MECHANISMS OF BACTERIAL PATHOGENICITY

The main characteristics of pathogenic bacteria that underlie the mechanisms by which they cause disease are:

- Colonization and infiltration of host tissues: the colonization of a specific host niche usually represents the first stage of infection. This may result in the carriage state or may lead to infiltration of the host tissues. The latter involves growth on or within host tissues, the ability to bypass or overcome host defense mechanisms, and the production of extracellular tissue-degrading exoenzymes.
- Toxin production: bacteria produce two categories of toxins, termed exotoxins and endotoxins. Exotoxins are released or secreted from bacterial cells and may act at tissue sites distant from the sites of bacterial infection, adhesion, and growth. Endotoxins are cell-associated structural components of the gram-negative bacterial envelope, which may be released from growing bacterial cells as blebs or from lysed cells (see Endotoxins). Hence, bacterial toxins, both soluble and cell-associated, may be transported by blood and lymph and induce cytotoxic effects at tissue sites remote from the original site of infection. Some bacterial toxins may also act at the site of colonization and play a role in promoting tissue invasion.

Colonization

The first stage of bacterial infection is colonization, which is essentially the establishment of the pathogen at a specific body site frequently followed by entry into host tissues. Pathogens usually colonize host tissues that are in contact with the external environment, for example the urogenital tract, the digestive tract, the respiratory tract, and the conjunctiva. Organisms that infect these sites have developed specific tissue-adherence mechanisms alongside the ability to overcome the local innate host defenses (see Host resistance to infection). This stage may, however, be bypassed as a consequence of tissue damage or introduction of medical devices, e.g. catheters.

ADHERENCE TO SURFACES

Bacterial adherence to host tissues involves at least two stages:

1. Nonspecific adherence. This physicochemical process can be considered as reversible attachment of the bacterium to the eukaryotic cell or tissue surface and involves nonspecific attractive forces that allow the bacterium to approach the eukaryotic cell/tissue surfaces. The interactions and forces involved include hydrophobic and electrostatic attractions, atomic and molecular vibrations resulting from fluctuating dipoles of similar frequencies between components of the bacterial and the host cell, Brownian movement, and bacterial cell recruitment or trapping by biofilm polymers (see Biofilms).
2. Specific adherence. This can be a reversible or permanent attachment of the microorganism to the cell or tissue surface. Specific adherence involves irreversible formation of many specific, noncovalent bonds between complementary adhesin and receptor molecules on each interacting surface. The latter must be accessible and arranged in such a way that many bonds form over the area of contact between the two cells. Once the bonds are formed, attachment under physiological conditions becomes virtually irreversible. Direct evidence that receptor and/or adhesin molecules mediate the specificity of adherence of bacteria to host cells or tissues has been derived from the competitive binding of bacteria to isolated receptors or receptor analogs in vitro. Purified bacterial adhesins and adhesin analogs that bind to eukaryotic cell/tissue surfaces have been shown to inhibit the interaction of bacteria with host cells. Such inhibition can also be achieved with purified receptors or antibodies to either the adhesins or to the eukaryotic receptor.

The eukaryotic receptors that have so far been identified are specific surface peptides or carbohydrates, which have functions in the host cell distinct from their functions as receptors for bacterial adhesins. Bacterial adhesins are macromolecular components of the bacterial cell envelope, and adhesins and receptors interact in a complementary and specific fashion.

HOST- AND SPECIES-SPECIFIC TROPISMS

It has long been recognized that bacteria exhibit different degrees of colonization or adherence tropisms. These can be broadly subdivided into (1) tissue- and host-specific tropisms and (2) species-specific tropisms.

1. Tissue and host tropisms. Some bacteria show a preference for certain tissues and specific hosts. For example, uropathogenic *Escherichia coli* adherence

patterns are determined by the binding specificity of the PapG adhesin (a component of the pyelonephritis-associated pili (Pap)) and the differential distribution of the receptor isotypes in different hosts and tissues. Three different *papG* alleles exist in uropathogenic *E. coli* (class I, II, III). Each binds with a different specificity to distinct receptor isotypes, with class II being the allele predominantly associated with pyelonephritis, and class III being correlated with human cystitis. PapG binds to the Gal-α-1-4Gal-containing glycolipids present on the surface of human kidney epithelial cells, allowing the bacteria to gain a foot-hold in the tissue and resist displacement by the mechanical and physical forces operating within the kidney. The glycolipid receptor for PapG consists of a digalactoside core linked via a β-glucose residue to a ceramide group that anchors the receptor within the membrane. This minimum receptor isotype is called globotriasylceramide (GbO3). The various members of this receptor family differ by the addition of sugar residues distal to the Gal-α-1-4Gal core of GbO3. The addition of a single GalNAc sugar to GbO3 creates GbO4 (globoside), whereas the addition of two GalNAc sugars to GbO3 creates the Forssman antigen (GbO5) (Dodson et al. 2001).

2 Species-specific tropisms. Some pathogenic bacteria infect only certain animal species, e.g. *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *E. coli* (expressing CFA I and CFA II), and group A streptococci are limited to infections of humans, whereas enteropathogenic *E. coli* K-88 infections are limited to pigs and *E. coli* K-99 strains predominantly infect calves. Although adhesin type and receptor specificity play an important role, it should be noted that other factors, such as nutritional requirements, may contribute to species-specific tropisms (see Iron scavenging). It should also be noted that certain strains or races within a species are genetically immune to specific pathogens. A good example is the lack of susceptibility of certain pig breeds to *E. coli* K-88 infections (Jann and Jann 1992). Although the differing nutritional or physiological conditions encountered in different animals is likely to influence the course of an infection, the outcome is related much more closely to the structural differences between, or absence of, a given eukaryotic receptor for a specific bacterial adhesin.

EXAMPLES OF BACTERIAL ADHESINS AND THEIR RECEPTORS

The adhesins of *E. coli* are varied and include pili, fimbriae, fibrillar, and afimbrial adhesins. A single strain of *E. coli* may be able to express several distinct adhesins encoded by distinct regions of the chromosome or of plasmids. This genetic diversity permits this organism to adapt to its changing environment and exploit new opportunities presented by different host surfaces. Many of the adhesive fimbriae of *E. coli* have probably evolved from fimbrial ancestors resembling type 1 and type 4 fimbriae. Type 1 fimbriae enable *E. coli* to bind to D-mannose residues on eukaryotic cell surfaces. Although the primary fimbrial subunit (FimA) is the major protein component of type 1 fimbriae, the mannose-binding site is located in a minor protein (FimH) located at the tips or inserted along the length of the fimbriae. By genetically varying the minor 'tip protein' adhesin, the organisms gain the ability to adhere to different receptors. For example, tip proteins on Pap pili recognize a digalactose residue, while tip proteins on S-fimbriae recognize sialic acid. Differential binding can also be achieved by allelic variation of the *fimH* gene, for example, in *Salmonella enterica* serovar Typhimurium (Boddicker et al. 2002). The fibronectin-binding *E. coli* fimbriae known as curli (Olsén et al. 1989) are unusual since they are assembled via an extracellular nucleation precipitation pathway (Smyth et al. 1996). Production of curli increases internalization of bacterial cells by eukaryotic cells and triggers events leading to septic shock. Since curli also promote clumping of bacterial cells in culture and binding to abiotic surfaces, they are important for biofilm formation (Chirwa and Herrington 2003) (see Biofilms). Although *E. coli*, *S. enterica* serovars Typhimurium and Enteriditis, and *Shigella* spp. have the genes required for curli synthesis, the expression of curli is not common to all strains due to insertion sequence disruptions, deletions, or other mutations. Unlike natural isolates of enterohemorraghic, enterotoxigenic, and sepsis *E. coli* strains, enteroinvasive and enteropathogenic (EPEC) strains do not produce curli. EPEC combine the adhesive properties of bundle-forming pili (a type IV fimbria) (Tobe and Sasakawa 2001) with the intimate adherence mediated by effectors secreted by the type III secretion pathway (see Protein secretion) (Delahay et al. 2001). In addition, the flagella of EPEC can function as an adhesin for binding to mammalian cells, although the nature of the eukaryotic receptor(s) is not known (Girón et al. 2002). A fimbrial adhesins include Afa-I and Afa-III, which are made along with the Dr hemagglutinin and fimbrial F1845 adhesin by Afa/Dr diffusely adhering *Escherichia coli* (DAEC). The mechanism by which Afa/Dr DAEC infection is linked to inflammatory bowel diseases is currently unknown, however utilization of a glycosylphophatidylinositol-anchored protein (the complement-regulating decay-accelerating factor (DAF) or CD55) as a receptor for Afa/Dr adhesions offers one possible explanation. Afa/Dr DAEC strains recognize the short consensus repeat 3 (SCR3) domain of DAF, which plays a pivotal role in the regulatory function of DAF. In so doing, they induce a cascade of responses in T84 cells, including interleukin 8 (IL-8) production and polymorphonuclear leukocyte transepithelial migration.

Production of tumor necrosis factor-α (TNF-α) and IL1β follows, which upregulates DAF expression, thus increasing the brush border adhesion of Afa/Dr leading to structural and functional lesions (Bétis et al. 2003).

Pseudomonas, *Vibrio*, and *Neisseria* possess a fimbrial protein subunit that contains methylated phenylalanine at its amino terminus. These type IV pili have been established as virulence determinants of *Pseudomonas aeruginosa* lung infections in cystic fibrosis patients, and the receptor for such fimbriae produced by *N. gonorrhoeae* is the surface glycoprotein CD46 on urogenital cells (Tobiason and Seifert 2001). The major virulence factors of toxigenic *Vibrio cholerae* are cholera toxin (CT), which is encoded by a lysogenic bacteriophage (CTXϕ), and toxin-coregulated pilus (TCP), which was also reported to be encoded on a filamentous phage genome. TCP is a type IV bundle-forming pilus essential for colonization and also serves as the receptor for CTXϕ. Somewhat controversially, TCP has also been proposed to be a coat protein for a novel filamentous phage (Davis and Waldor 2003).

Gram-positive bacteria, such as *Staphylococcus aureus,* possess multiple cell wall proteins (microbial surface components recognizing adhesive matrix molecules (MSCRAMM)) which facilitate binding to host cells and tissues, thus promoting attachment of bacteria to surfaces. These include the fibronectin-binding proteins FnbA and FnbB, which promote adherence to host tissues and are essential for inducing the uptake of staphylococci into epithelial and endothelial cells. Other MSCRAMM can override the loss of fibronectin binding and allow adherence to host cells but not lead to efficient internalization into eukaryotic cells (Bayles and Bohach 2001).

Other gram-postive pathogens, such as Group A streptococci and *Streptococcus pyogenes*, also display cell-surface fibronectin-binding proteins (Bisno et al. 2003). The fibronectin binding proteins (e.g. F, M1 and M3) of *Str. pyogenes* in conjunction with lipotechoic acid (LTA) are involved in promoting attachment to the oral mucosa and buccal epithelial cells, where LTA loosely tethers streptococci to epithelial cells, whereas M proteins secure a much stronger, less reversible association.

Treponema pallidum, the causative agent of syphilis, has three related surface adhesins (P1, P2, and P3), which bind to a four-amino acid sequence (Arg-Gly-Asp-Ser) of the cell-binding domain of fibronectin. It is not clear whether *T. pallidum* uses fibronectin to attach to host surfaces or coats itself with fibronectin to avoid host defenses, such as phagocytic cells (Baughn 1987).

BIOFILMS

In most environmental niches, bacteria survive and multiply not as planktonic cells suspended in liquids but as surface-attached biofilms. These are complex communities of single or multiple species of microorganisms that develop on abiotic (e.g. rocks) and biotic (host mucosal tissues) surfaces. Since biofilms contaminate industrial pipelines, dental-unit water lines, catheters, ventilators, and medical implants, they act as a source of disease for humans, animals, and plants. They also represent a barrier to eradication as both the nature of the biofilm and the physiological state of bacterial cells within the biofilm confers high levels of resistance to antimicrobial agents.

Microbial development on surfaces is a dynamic stepwise process involving adhesion, growth, motility, and extracellular polysaccharide (EPS) production (Figure 1). Five distinct stages of biofilm development (namely (1) reversible attachment; (2) irreversible attachment; (3) maturation 1; (4) maturation 2; and (5) dispersion) (Sauer et al. 2002) culminate in a structured community sometimes characterized by mushroom and mound structures. Underlying this process is a genetically programmed series of events; however, bacteria appear to have evolved more than one pathway, probably due to particular environmental stimuli (growth media or substratum, etc.) triggering different developmental pathways. Despite this, all culminate with the same end point, i.e. a mature biofilm community (O'Toole 2003). For *P. aeruginosa*, biofilm formation involves the production of flagella and pili followed by the production of EPS. To become a member of the biofilm community, the bacterium must then differentiate into a biofilm-associated cell by repressing synthesis of the flagellum (O'Toole 2003; Watnick and Kolter 2000). Ultimately, however, flagella are produced once more to facilitate dispersal (Sauer et al. 2002).

Although redistribution of attached cells to form a structured community can be achieved by motility via flagella, pili, or fimbriae, this is not a prerequisite, since nonmotile organisms readily form biofilms, e.g. staphylococci, streptococci, and mycobacteria. As cells divide, daughter cells spread outward and upward from the attachment point to form cell clusters offering an alternative mechanism of biofilm formation. Surface-associated aggregation can also occur via the recruitment of single cells or cell flocs from the bulk fluid. Bacterial cells in biofilm microcolonies are held together by a slime-like matrix (EPS). This matrix is chemically complex, including polysaccharides, nucleic acids, and proteins. Intercellular adhesion within biofilms of *Staphylococcus epidermidis*, a major cause of medical device-related infections, is mediated by the polysaccharide intercellular adhesin (PIA). Synthesis of this linear glucosaminoglycan composed of *N*-acetylglucosamine in β-1,6-glycosidic linkages containing deacetylated amino groups and succinate and phosphate substituents requires expression of the *icaADBC* operon. These genes are subject to a complex regulatory control mechanism, which involves the alternative sigma factor σ^B, *icaR*, two other regulatory loci, plus phase variation due to IS element insertion. Cessation of PIA produc-

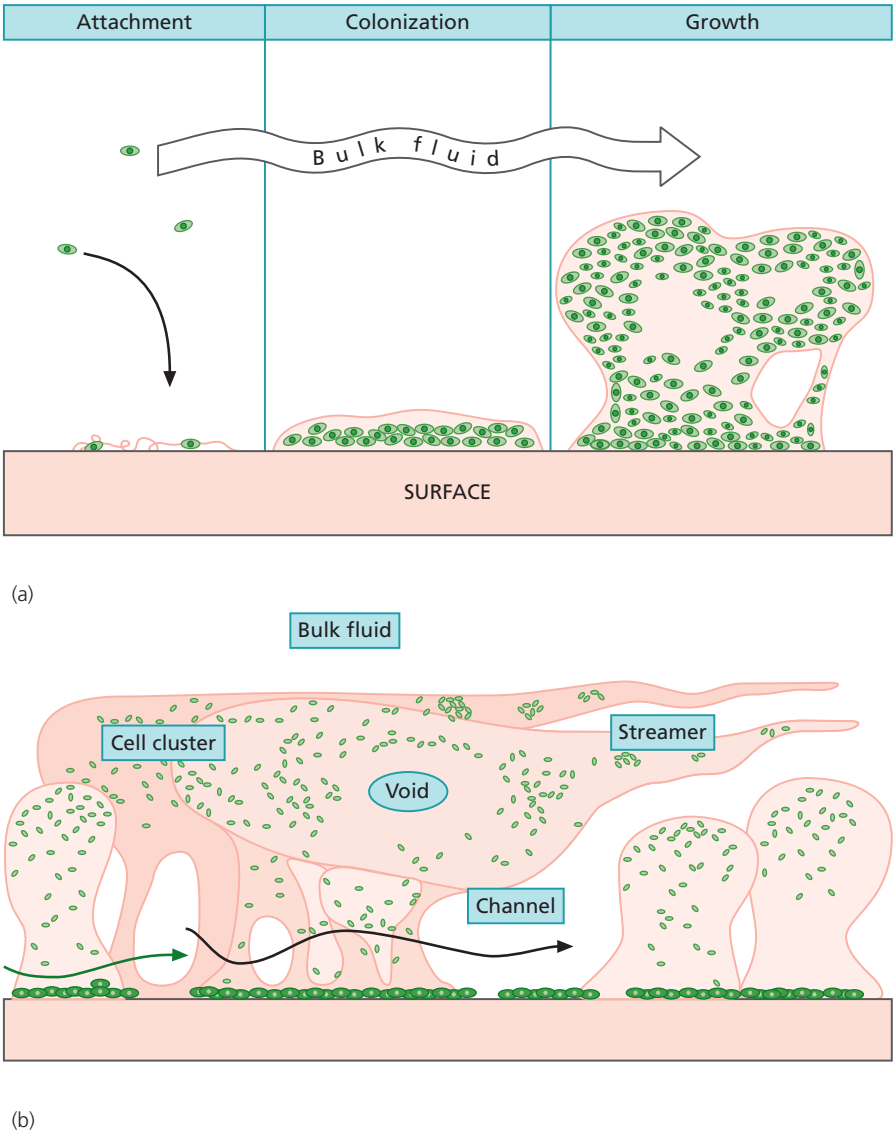

Figure 1 *Biofilm formation:* **(a)** *Bacteria attach to a surface and multiply. An extracellular polysaccharide is produced and the combined influence of this and the physical properties of the environment favor the development of complex structures resembling mounds and mushrooms. The bulk fluid flows between these structures through channels, and, if strong enough, streamer structures develop downstream.* **(b)** *Dispersal of detached bacterial cells finally occurs into the bulk fluid. tion by inactivational IS element insertion allows individual cells to leave the biofilm and colonize new surfaces (Dobinsky et al. 2003). Physical forces acting on the biofilm can also influence its structure, e.g. a faster flow can favor biofilm cell clusters, which tend to elongate in the downstream direction, forming filamentous 'streamers' (Hall-Stoodley and Stoodley 2002).

Proliferation

Bacterial proliferation within a colonization niche and also during the development of infection will depend on an ability not only to resist host defenses but also to acquire essential nutrients. Bacteria have therefore evolved a full complement of mechanisms for nutrient acquisition (e.g. to scavenge for carbon and nitrogen sources, phosphate, sulfur, and metal ions) and for the synthesis of complex organic molecules that cannot be scavenged from the local environment. Specific transport systems or cell-wall components capable of binding limiting substrates and transporting them into the bacterial cell are employed by both pathogenic and nonpathogenic bacteria. Pathogens that are highly host-adapted often dispense with biosynthetic pathways for complex organic molecules that can be obtained directly

from the host. For example, *H. influenzae* requires heme (X factor) and nicotinamide adenine dinucleotide (NAD^+; V-factor) for growth.

For almost all bacterial pathogens, iron is one indispensable nutrient, the lack of which exerts considerable influence on growth in vivo. Iron is a redox reactive metal and is required as a cofactor for many important metabolic enzymes and cytochromes. Although there is an abundance of iron in the extracellular tissue fluids of man and animals, the amount of free ionic iron is of the order of 10^{-9} M, a level that is far too low to support the growth of most microorganisms. The injection of animals with iron compounds results in an increased susceptibility to experimental infection when compared with untreated controls, so that the lethal dose of infecting microorganism required is greatly reduced. Iron is also the only metal cation known to be capable of abolishing the antibacterial activity of body fluids in vitro. The ability of the host to withhold iron thus contributes to host defense against infecting microorganisms and in extracellular tissue fluids depends on the host iron-binding glycoproteins transferrin and lactoferrin (see Iron scavenging). However, most pathogens multiply successfully in body fluids and cause infection in the absence of exogenously supplied iron either because they possess efficient iron scavenging mechanisms capable of removing transferrin-bound iron or by invading host cells where intracellular iron is more freely available.

IRON SCAVENGING

The most intensively investigated bacterial high-affinity iron-transport systems are based on siderophores. These are low-molecular-mass iron chelators that bind iron with high affinity and specificity. They are employed by both gram-negative bacteria such as *E. coli*, *Shigella* spp., *Salmonella* spp., and *P. aeruginosa* and gram-positive pathogens such as the staphylococci, mycobacteria, and corynebacteria. *Shigella* species employ at least three distinct iron-transport systems, two of which involve siderophores (aerobactin and enterobactin) and their associated outer-membrane receptor proteins. A third pathway required for the transport and utilization of iron in the form of heme is employed by shigellae growing intracellularly within epithelial cells. While the enterobactin iron-transport system is found in all *E. coli* strains so far examined, aerobactin production and heme transport are more often associated with pathogenic *E. coli* strains and the corresponding genetic loci are encoded on virulence plasmids, within pathogenicity islands, or on chromosomal regions with the potential for horizontal transmission.

Certain bacterial pathogens and notably *H. influenzae* and *N. meningitidis* use a siderophore-independent receptor-mediated iron-uptake system that involves a direct interaction between a bacterial cell-surface receptor (consisting of two transferrin-binding proteins, TbpA and TbpB) and transferrin. These receptor-based mechanisms are further distinguished from siderophore-mediated mechanisms by their high degree of specificity for the iron-binding glycoprotein of the natural host; humans are the only natural reservoir for *N. meningitidis*, which will only bind human transferrin, while the pig pathogen *Actinobacillus pleuropneumoniae* can use porcine but not human transferrin as an iron source.

Apart from sequestering transferrin-bound iron, many pathogens have also evolved mechanisms for acquiring iron from heme-containing proteins (such as hemoglobin) or from heme- and hemoglobin-binding proteins (hemopexin and haptoglobin, respectively). These involve either specific surface receptors or secreted proteins such as HasA of *P. aeruginosa* and *Serratia marcescens*. The latter consists of an outer-membrane receptor (HasR) and a type I secretion apparatus (see below under Subversion of host cell signal transduction and on protein secretion) in addition to the extracellular heme-binding protein. HasR can bind and transport free heme or heme bound to hemoglobin, in a manner enhanced by the presence of HasA. Thus, it appears that the HasA–HasR interaction, rather than recognition of heme, is important for ligand uptake (Clarke et al. 2001).

For both high-affinity iron- and heme-scavenging systems in gram-negative bacteria that involve outer membrane receptor proteins, a common feature is the requirement for the energy-transducing protein TonB to promote the uptake of iron across the outer membrane together with an ABC transporter for transporting the iron–ligand complex across the periplasm and cytoplasmic membrane. Gram-positives need only the ABC transporter and a binding protein, which is usually a cytoplasmic membrane anchored lipoprotein

Motility

To establish infection in or on a susceptible host, a pathogen must reach a suitable infection site or breach in host tissues. For example, at mucus membranes a pathogen may need to penetrate the mucus blanket and subsequently adhere to the epithelium. Movement through mucus to the epithelial cells may be dependent on chemoattractants present in host tissues, the motility organelles on the bacterium (see below), and possibly mucus-degrading enzymes (see Infiltration of host tissues).

Motility can be achieved through the retraction of surface appendages (type IV pili-mediated twitching motility) (Mattick 2002) or rotation of specialized motors (flagella-mediated swimming) (Josenhans and Suerbaum 2002). Flagella are assembled by a machinery with significant similarity to the type III secretion pathway (see below under Subversion of host cell signal transduction and on protein secretion). The control of this machinery and the structural assembly of the flagella

are subject to a complex hierarchical regulation. The flagellum comprises structurally of a hook filament protruding from the basal body, which anchors it to the cell membranes. Extending from this is the long rigid filament (Aldridge and Hughes 2002). Bacteria may have single or multiple flagella, which can be arranged in a polar fashion or distributed over the entire cell surface. Flagella rotation propels the bacterium, and this forward motion is punctuated with tumbling, during which reorientation may occur to enable bacteria to preferentially spread in certain directions (chemotaxis). The flagella of *E. coli* rotate in a counterclockwise direction to achieve a forward motion, and switch to a clockwise direction to effect stopping and tumbling (Berg 2003). Other bacteria, e.g. *Rhodobacter spirillum*, achieve this control by periodically ceasing flagella rotation (Armitage 1999).

Swarming is a specialized form of bacterial motility that is characteristic of species belonging to genera such as *Proteus, Vibrio*, *Bacillus*, and *Clostridium* but is also exhibited by *Serratia*, *Escherichia*, *Salmonella*, and *Yersinia* spp. Depending on the organism, swarming depends on flagella and pili, as well as surface components such as polysaccharides and surfactants, and involves differentiation of vegetative bacterial cells into hyperflagellate swarm cells that undergo rapid and coordinated population migration across solid surfaces. For pathogens such as *Proteus mirabilis*, swarming facilitates ascending colonization of the urinary tract and entry into host cells (Fraser and Hughes 1999).

Infiltration of host tissues

Motility is not the sole requirement for successful relocation. There are numerous factors that mediate the penetration of bacteria deep into host tissues. These factors function by altering the integrity of the tissues by degrading the extracellular matrix or tissue cells or by travelling directly through cell layers after uptake directly into mammalian cells, a process that leads to either tissue necrosis or programmed cell death (apoptosis). Such determinants are often termed 'spreading factors' and are usually bacterial enzymes that affect the physical properties of tissue matrices and intercellular spaces, thereby promoting the spread of the pathogen (see Table 1).

Once in contact with eukaryotic cells, bacteria may be taken up by the host cell or may mediate their own internalization to proceed further. Bacteria-mediated uptake into nonphagocytic host cells may be achieved by either bacterial surface proteins (invasins), which interact with specific receptors on the host cell (e.g. internalin A and B binding to E-cadherin during uptake of *Listeria monocytogenes*), or bacterial proteins injected into the host cell cytoplasm, which trigger membrane ruffling and concomitant bacterial uptake by macropinocytosis (e.g. *Salmonella* or *Shigella*) (see Subversion of host cell signal transduction). The invasin-mediated 'zipper' mode of entry is achieved by unrelated proteins in different bacteria (e.g. *Listeria* internalins and *Yersinia* invasin), whereas the mediators of the 'trigger' mechanism of uptake used by *Shigella* (Ipas) and *Salmonella* (Sips) are similar. All mechanisms proceed to localization of the bacterium within a membrane-bound vacuole. This vacuolar compartment is acidic, is poor in nutrients, and undergoes progressive vesicle fusion with early endosomes, late endosomes, and lysosomes that contain potent lytic enzymes. Some pathogens have evolved mechanisms to modify the vacuole or its process of maturation and remain localized within the vacuole, e.g. *Mycobacterium tuberculosis* and *Salmonella* spp. *M. tuberculosis* recruits tryptophan-aspartate-containing coat protein (TACO) to the membrane of the phagosome, thus mimicking the plasma membrane and thereby preventing maturation into, or fusion with, lysosomes (Pieters and Gatfield 2002). In contrast, *S. enterica* serovar Typhimurium appears to deliver effector molecules via the type III secretion machinery (*Salmonella* pathogenicity island; SPI-2) (see Subversion of host cell signal transduction) into the cytosol, which disrupt recruitment of the components of the noxious host enzyme NADPH oxidase to the phagosome (Amer and Swanson 2002).

Other pathogens escape from the vacuole into the cytosol, e.g. *Listeria monocytogenes*, *Shigella flexneri*, and rickettsiae (O'Riordan and Portnoy 2002). To escape from phagosomes, *L. monocytogenes* produces the pore-forming cytolysin listeriolysin O (LLO). The combined action of LLO with phosphatidylinositol-specific phospholipase C (PI-PLC) and phophatidylcholine-specific phospholipase C (PC-PLC) disrupts the phagosomal membrane leaflet, although the underlying mechanism employed is uncertain. *Sh. flexneri* appear to use the hemolytic activity of IpaB and possibly also the *icsB* gene product to achieve liberation from the phagosome (Goebel and Kuhn 2000).

Many cytosolically replicating intracellular bacteria possess the ability to spread from the primary infected cell into its neighbors. This ability depends on the polymerization of cellular actin at one bacterial cell pole mediated by a specific bacterial surface protein (ActA for *L. monocytogenes*; IcsA, IcsB, and OpaB for *Sh. flexneri*). *L. monocytogenes*, for example, move ahead of an actin comet tail at a speed of approximately 0.3 μm/s, upon contact with the host cell plasma membrane, a bacterium-containing protrusion is formed, which is internalized by the adjacent cell. The bacterium then lyses the two plasma membranes surrounding it in the newly infected cell to continue the cycle (see Figure 2) (Cossart and Lecuit 1998). Although *Sh. flexneri* spreads in a similar fashion, the proteins that mediate this phenomenon are unrelated to those of listeria (Bourdet-Sicard et al. 2000). This form of dissemination circum-

Table 1 *Spreading factors that aid bacterial invasion of tissues*

Spreading factor	Producing bacteria	Comments
Hyaluronidase	Streptococci, staphylococci, clostridia	Attacks the interstitial cement of connective tissue by depolymerizing hyaluronic acid
Collagenase	*Clostridium histolyticum*, *Clostridium perfringens*	Breaks down collagen, the framework of muscles, facilitating the development of gas gangrene
Neuraminidase	Intestinal pathogens: *Vibrio cholerae*, *Shigella dysenteriae*	Degrades neuraminic acid (sialic acid), an intercellular cement of the epithelial cells of the intestinal mucosa
Streptokinase and staphylokinase	Streptococci and staphylococci	Kinase enzymes that convert inactive plasminogen to plasmin, which digests fibrin and prevents clotting of the blood. The relative absence of fibrin in a spreading bacterial lesion allows more rapid diffusion of the infectious bacteria throughout the tissues of the host
Enzymes that cause hemolysis and/or leukolysis	Staphylococci (leukocidins), Streptococci (streptolysin)	Insert into membranes forming a pore that results in cell lysis, or enzymatically attack phospholipids, which destabilizes the membrane. They may be referred to as lecithinases or phospholipases, hemolysins (if they are able to lyse red blood cells), or leukocidins and streptolysin (lyse phagocytes and their granules)
Phospholipases	*Clostridium perfringens* (α toxin)	Hydrolyze phospholipids in cell membranes by removal of polar head groups
Lecithinases	*Clostridium perfringens*	Destroy lecithin (phosphatidylcholine) in cell membranes, leading to cell lysis
Hemolysins	Staphylococci (α toxin), Streptococci (streptolysin), Clostridia spp.	Channel-forming proteins or phospholipases or lecithinases that destroy red blood cells and other cells, such as phagocytes through cell lysis
Staphylococcal coagulase	*Staphylococcus aureus*	Cell-associated and diffusible enzyme that converts fibrinogen to fibrin, which causes clotting. Cell-associated coagulase may also provide an antigenic disguise by causing clotted fibrin to deposit on the cell surface. Also in the case of a staphylococcal lesion encased in fibrin, e.g. a boil or pimple, bacterial cells may be resistant to phagocytes or tissue bactericides or even antibiotics, which might be unable to reach their bacterial target
Extracellular digestive enzymes	Heterotrophic bacteria	Including proteases, lipases, glycohydrolases, and nucleases. May aid in invasion either directly or indirectly by damaging the cells of the tissue, or contribute to bacterial nutrition or metabolism
Toxins with short-range effects related to invasion	*Bordetella pertussis* (adenylate cyclase), *Bacillus anthracis*, (edema factor component of anthrax toxin)	Immediate effects on host cells that promote bacterial invasion of host tissues by causing increased levels of cAMP and disruption of cell permeability. These toxins may contribute to invasion through their effects on macrophages or lymphocytes in the vicinity, which are playing an essential role to contain the infection or on the cells of the tissue themselves

cAMP, cyclic adenosine monophosphate.

vents both the humoral and complement-mediated host defenses (see Host resistance to infection).

Obligate intracellular bacteria have taken these measures to the extreme. *Rickettsia prowazekii* (the causative agent of epidemic typhus), for example, is maintained in a cycle involving human and body lice (*Pediculus humanus*) cells, and is transmitted through direct contact of humans with contaminated body louse feces. Following entry into cells via induced phagocytosis, *R. prowazekii* escapes from the phagosome into the cytoplasm. Upon cell lysis, spread can continue to neighboring cells in a similar fashion; however, the related *Rickettsia rickettsii* (causative agent of Rocky Mountain spotted fever) achieves intracellular cell–cell spread powered by actin-based motility similar to that of *Listeria* and *Shigella* (Hackstadt 1998).

Avoidance of host immune defenses

During the processes of colonization and tissue invasion, pathogens must avoid host defenses (see Host resistance to infection). While some bacteria adopt an intracellular lifestyle (see Infiltration of host tissues) to evade defense mechanisms by their internal location, others employ

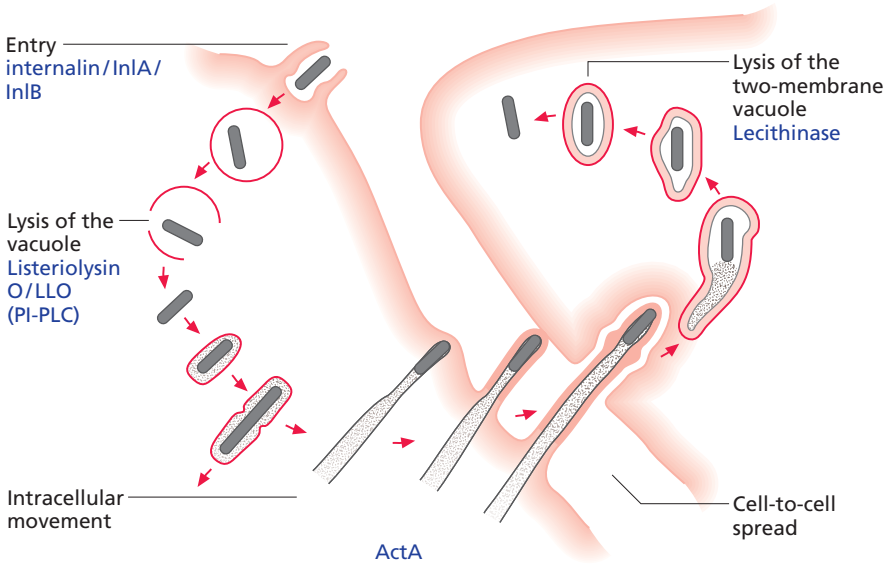

Figure 2 *Schematic representation of the cell infectious process of* Listeria monocytogenes. *Bacterial factors are indicated in blue. (Redrawn from Cossart and Lecuit 1998)*

protective surface coatings, e.g. exopolysaccharides and lipopolysaccharides (LPS) (see Toxins), which can be antiphagocytic and, in the case of surface macromolecules, which mimic those of the host, function as 'camouflage.'

Exopolysaccharides include discrete capsules (e.g. the capsular polysaccharides (sometimes called K-antigens) of *E. coli*, *Klebsiella pneumoniae, Streptococcus pneumoniae*, and *S. aureus*) and the loosely associated slime polysaccharides produced by mucoid bacteria. Exopolysaccharides form highly hydrated water-insoluble gels composed of either homo- or heteropolysaccharides. The former consists of a single sugar monomer (e.g. the levans and dextrans of many oral streptococci), and the latter of repeating oligosaccharide units of more than one monomer. Many exopolysaccharides are acidic due to the possession of carboxyl groups, either from acidic sugars, such as uronic acids or neuraminic acid, or from nonsugar substituents, such as pyruvyl, acetyl, and formyl groups. Their acidic nature is reflected in many of their properties. A few of the bacilli (e.g. *Bacillus anthracis*) have a capsule made up of a single amino acid, poly-D-glutamic acid. In physical chemistry and function, however, it is similar to the polysaccharide capsules.

In the environment, the highly hydrated nature of exopolysaccharides offer bacteria protection from desiccation and a potential mechanism for trapping nutrients, although they are not employed as a reserve carbohydrate food source for use during starvation. Exopolysaccharides do, however, contribute to virulence in two different ways. First, they may contribute to bacterial adhesion. This is particularly obvious in the cariogenic organism, *Streptococcus mutans*. This bacterium can synthesize a dextran-like branched water-insoluble homopolymer of glucose from dietary sucrose. This forms a glutinous layer on the surface of teeth and contributes to the matrix of dental plaque. Second, capsular polysaccharides protect bacteria from phagocytic cells (including amoebae in the environment). This is because capsulate or slime-producing bacteria growing as aggregated microcolonies or biofilms cannot be engulfed for steric reasons, i.e. they are too large to be internalized. Mucoid *P. aeruginosa* strains, which produce the exopolysaccharide alginate in the lungs of infected individuals with cystic fibrosis (CF), provide a good example of this. In CF, lung damage arises in part from the tissue-damaging agents, e.g. elastase released by neutrophils unable to engulf the bacteria. Exopolysaccharides also render bacterial cells more resistant to phagocytic engulfment by increasing surface hydrophilicity, and blocking the action of complement (see LPS and virulence).

Several bacterial pathogens produce exopolysaccharide capsules, the chemical structure of which mimics a host tissue surface antigen. This protects the organism from the immune system by appearing to the host as 'self.' Perhaps the best known examples are the K1 capsule of *E. coli* and the immunologically and structurally identical capsule of *N. meningitidis* group B. These organisms have capsules of α-2,8-linked *N*-acetylneuraminic acid, which is partially *O*-acetylated and immunologically crossreacts with neonatal neural cell adhesion molecules.

Many pathogens have a highly organized proteinaceous surface layer, the S layer. The role of this in pathogenesis has not been fully elucidated, but the S-layer of *Aeromonas salmonicida* can provide resistance to the bactericidal activity of complement, that of *Rickettsia prowazekii* is responsible for humoral and cell-mediated immunity, and that of *Lactobacillus acidophilus* is required for adhesion to the intestinal epithelium (Sara and Sleytr 2000).

Toxins

Toxins are frequently responsible for the tissue damage characteristic of bacterial infections and hence make a significant contribution to pathogenicity. Indeed, for some pathogens, the adminstration of the toxin alone is sufficient to reproduce the same disease as that resulting from infection by the producer organism, e.g. botulism.

PROTEIN EXOTOXINS

Exotoxins are typically proteins secreted or released by bacteria during growth. They are usually produced only by a single bacterial species within a genus. For example, *Clostridium tetani* produces tetanus toxin, whereas *Clostridium botulinum* produces botulinum toxin. Usually, virulent strains of the bacterium produce the toxin while avirulent strains do not, indicating that in many cases the exotoxin is a major determinant of virulence. Bacterial exotoxins are produced by both gram-positive and gram-negative bacteria and have highly specific targets and modes of action. The target may be a component of specific cells, tissues, or organs and usually the site of toxin damage indicates the location of the substrate for that toxin. Terms such as enterotoxin, neurotoxin, leukocidin, and hemolysin are often used to indicate the target sites for protein toxins. Many protein toxins exhibit very specific cytotoxic activities, e.g. tetanus or botulinum toxins attack specific cell types (Table 2). However, other toxins, such as those produced by staphylococci, streptococci, clostridia, etc., have a broad cytotoxicity causing necrotic tissue cell death. Toxins that are phospholipases are particularly nonspecific in their cytotoxicity because they cleave phospholipids (which are components of all host cell membranes), resulting in the death of the cell by leakage of cellular contents. This is also true of pore-forming hemolysins and leukocidins.

A few highly potent protein toxins can kill the host in the absence of the producing organism and are known as lethal toxins. Even though the tissues affected, and the target sites for such toxins (e.g. anthrax toxin) may be known, the precise mechanism by which death occurs is not always understood.

As 'foreign' substances to the host, most protein toxins are strongly antigenic. In vivo, specific antibodies (antitoxins) can neutralize the actions of these bacterial proteins. Also, protein toxins are inherently unstable and can lose their toxic properties while retaining their antigenicity. This was first discovered by Paul Ehrlich who coined the term 'toxoid'. The formation of toxoids can be accelerated by treatment with a variety of chemical reagents, including formaldehyde. The resulting toxoids can be used for immunization against diseases caused by the corresponding pathogen where the primary determinant of bacterial virulence is the toxin.

A + B subunit toxins

Many protein toxins, notably those that act intracellularly, consist of two components termed A and B. Subunit A is responsible for the enzymatic activity of the toxin at the target site. Subunit B facilitates the binding of the toxin to a specific receptor on the host cell membrane and subsequent internalization of the A subunit. The enzymatic component is not active until it is released from the native toxin. Purified A subunits are enzymatically active but lack the ability to bind to host cells. Isolated B subunits may bind to target cells, but they are nontoxic. Toxin subunits may be synthesized and arranged in a variety of ways, for example A-B or A-5B indicates that subunits are synthesized separately and associated by noncovalent bonds, whereas A/B denotes that the subunit domains are formed from a single protein that may be separated only by proteolytic cleavage. The notation A + B indicates that the separate protein subunits interact at the target cell surface to form the toxin. More than one binding subunit is indicated as, 5B for example, which shows that the binding domain is composed of five subunits.

Attachment and entry of toxins

There are at least two mechanisms for toxin entry into target cells. In both cases, a large protein molecule must insert into and cross a membrane lipid bilayer. This activity is reflected by the ability of most A/B native toxins, or their B components, to insert into artificial lipid bilayers, creating ion-permeable channels. For direct entry, the B subunit of the native toxin binds to a specific receptor on the target cell and induces the formation of a pore in the membrane, through which the A subunit is transferred into the cell cytoplasm. The second mechanism relies on the native toxin binding to the target cell and the A + B structure is taken into the cell by the process of receptor-mediated endocytosis. The toxin is internalized in a membrane-enclosed vesicle called an endosome. H^+ ions entering the endosome lowers the internal pH, which causes the A + B subunits to separate. The B subunit effects the release of the A subunit from the endosome by forming a pore, facilitating association with its cellular target in the

Table 2 *Examples of two-component (A-B) exotoxins with intracellular targets*

Exotoxin	Comments
Adenylate cyclase toxin of *Bordetella* spp. Chromosomally encoded	Activated by eukaryotic intracellular calmodulin. Catalyzes conversion of ATP to cAMP, which perturbs cellular activity, inhibiting leukocyte chemotaxis and activity
Anthrax toxin of *Bacillus anthracis* Plasmid-encoded	Comprises three separate proteins, protective antigen (PA), edema factor (EF), and lethal factor (LF) EF + PA causes an increase in intracellular cAMP level, resulting in edema (fluid accumulation) LF + PA is a potent cytolethal toxin causing death of host cells and ultimately death of host
Botulinum toxins of *Clostridium botulinum* Phage-encoded	Comprises seven antigenically distinct toxins designated A to G. Among the most potent of all biological toxins of bacterial origin. The B-subunit binds to neuroreceptor gangliosides on cholinergic neurons, while the A-subunit irreversibly inhibits release of the stimulatory neurotransmitter acetylcholine, at muscle–nerve junctions, resulting in a paralysis and death
Cholera toxin from *Vibrio cholerae* Chromosomally encoded, A-5B structure	The B-subunit binds to GM_1 ganglioside receptors on the surface of small intestinal enterocytes. Reduction of the disulfide bond in the A-subunit activates A_1 fragment that ADP-ribosylates guanosine triphosphate (GTP)-binding protein (G_s) by transferring ADP-ribose from nicotinamide adenine dinucleotide (NAD). The ADP-ribosylated GTP-binding protein activates adenyl cyclase, resulting in an increase in intracellular cAMP, which triggers a profound movement of electrolytes (sodium, potassium, bicarbonate) and water into the lumen of the gut, leading to a profuse life-threatening diarrhea. In addition, the elevated cAMP levels in the gut cells also block the uptake of any further sodium and chloride from the lumen of the small intestine, ultimately resulting in hypovolemic shock and death in the absence of fluid and electrolyte replacement therapy
Diphtheria toxin from *Corynebacterium diphtheriae* Phage-encoded A-B structure	The toxin acts by ADP-ribosylation of intracellular targets, thereby inhibiting cell protein synthesis by catalyzing transfer of ADP-ribose from NAD to elongation factor-2 (EF-2)
Exotoxin A from *Pseudomonas aeruginosa* Chromosomally encoded	Very similar to diphtheria toxin
Heat-labile enterotoxins (LT) from enterotoxigenic *Escherichia coli* (ETEC) Plasmid-encoded A-5B structure	LT comprises two types (LT-I and LT-II). LT-1 is associated predominantly with human disease, while LT-II is produced only by strains isolated from animals. These toxins are very similar to cholera toxin
Pertussis toxin from *Bordetella pertussis* Chromosomally encoded A-5B structure	Different B-subunits where the S2 (B) subunit binds a glycolipid receptor on ciliated respiratory cells while the S3 (B) subunit binds to glycolipids on phagocytes. The S1 or A subunit inhibits cellular signal transduction via ADP-ribosylation of GTP-hydrolyzing protein (G_i), causing unregulated adenylate cyclase and large increases in cellular cAMP levels, resulting in hypersecretion of respiratory secretions, mucus, and paroxysmal cough. It is also known to inhibit leukocyte chemotaxis and activity
Shiga toxin of *Shigella dysenteriae* Chromosomally encoded A-5B structure	This very potent toxin has a similar mode of action to ricin, a toxin derived from castor beans. The B-subunit binds to Gb_3 glycolipid receptor on the surface of target cells. The A-subunit blocks protein synthesis by preventing binding of aminoacyl-transfer RNA through cleavage of the 28S rRNA from 60S ribosomal subunit
Shiga-like toxins of enterohemorrhagic *Escherichia coli* (EHEC) and *Shigella* spp. Phage-encoded A-5B structure	Two forms (SLT-I and SLT-II) in EHEC. SLT-I is identical to *S. dysenteriae* shiga toxin, with the exception of a single amino acid, while SLT-II has approximately 60% homology with shiga toxin. The B-subunit binds to target cell glycolipid globotriaosylceramide. The A-subunit is cleaved and the resulting A_1 fragment binds to 28S rRNA of 60S ribodomal subunit, thereby blocking protein synthesis in the same way as shiga toxin

(*Continued over*)

Table 2 *Examples of two-component (A-B) exotoxins with intracellular targets (Continued)*

Exotoxin	Comments
Tetanus toxin of *Clostridium tetani*Plasmid-encoded	This potent toxin is not secreted but is released upon lysis of the bacterial cell. The binding domain (B) binds to neuroreceptor gangliosides (GD_{1b}). The A-subunit is a zinc-dependent endopeptidase, which is internalized and migrates from peripheral nerves to central nervous system, across the synapses to presynaptic nerve endings this constitutes what is known as retrograde transport, i.e. against the normal direction of nerve impulses. Once at its target location, it accumulates in vesicles and irreversibly blocks the release of inhibitory transmitters. This results in continuous stimulation of muscles by excitatory neurotransmitters, resulting in spastic paralysis (spasms of bulbar and paraspinal muscles) with trismus (lockjaw; spasms of the masticatory muscles), risus sardonicus (spasms of the masseter muscles), and opisthotonos (spasms of back and neck muscles)

ADP, adenosine diphosphate; ATP, adenosine triphosphate; AMP, cyclic adenosine monophosphate; NAD, nicotinamide adenine dinucleotide.

cytoplasm. The B subunit remains in the endosome and is recycled to the cell surface.

Many of the genes encoding toxin production are located on plasmids or on lysogenic bacteriophages. Thus, genetic exchange in bacteria by conjugation and transduction can mobilize these genetic elements between different strains of bacteria and, therefore, may play a role in spreading pathogenic potential to other bacteria; see Table 2 for further examples of two-component exotoxins (Lahiri 2000).

Superantigens (type I toxins)

Conventional antigens are engulfed by antigen-presenting cells (APC), degraded into epitopes, e.g small peptides, and presented to the peptide groove of MHC-II molecules, where they are recognized only by specific T4-helper cells having a receptor (TCR) with a complementary shape. Superantigens (see Table 3), however, bind directly to the outside of the MHC-II molecules and are recognized by T4-lymphocytes. This activation of very large numbers of T4-lymphocytes results in the secretion of excessive amounts of interleukin-2 (IL-2), as well as the activation of self-reactive T-lymphocytes. High levels of IL-2 in the systemic circulation result in fever, nausea, vomiting, diarrhea, and malaise. Excess stimulation of IL-2 secretion can also result in the production of other cytokines such as TNF-α, interleukin-1 (IL-1), IL-8, and platelet-activating factor (PAF) and can lead to the same endothelial damage, acute respiratory distress syndrome, disseminated intravascular coagulation, shock, and multiple organ system failure observed with LPS and other bacterial cell-wall components (see Endotoxins). Activation of self-reactive T-lymphocytes can also lead to autoimmune disease (Llewelyn and Cohen 2002).

ENDOTOXINS

Endotoxins are bacterial cell-envelope components that are not actively secreted by the cell but can be shed as membrane blebs or vesicles into the bloodstream during the course of infection. They are exemplified by the lipooligosaccharides (LOS) and LPS found in the outer membrane of gram-negative bacteria. They are toxic to most mammals and, regardless of the bacterial source, all endotoxins produce the same range of biological effects. The injection of living or killed gram-negative cells, or purified LPS, into experimental animals causes a wide spectrum of nonspecific pathophysiological reactions,

Table 3 *Examples of superantigens*

Superantigen	Associated pathogen	Effect on host
Toxic shock syndrome toxin-1 (TSST-1)	Some strains of *Staphylococcus aureus*	Toxic shock syndrome (TSS): excessive cytokine production leads to fever, rash, and shock
Streptococcal pyrogenic exotoxin (Spe)	Rare invasive strains and scarlet fever strains of *Streptococcus pyogenes* (group A β streptococci)	Toxic shock-like syndrome (TSLS): excessive cytokine production leads to fever, rash, and shock
Staphylococcal enterotoxins (SE)	Many strains of *Staphylococcus aureus*	Food poisoning: excessive IL-2 production results in fever, nausea, vomiting, and diarrhea (vomiting may also be due to these toxins stimulating the vagus nerve in the stomach lining)
Hormone analog (Sta; heat-stable toxin)	Enterotoxigenic *Escherichia coli* (ETEC)	Binds to guanylate cyclase on intestinal epithelial cells, stimulating the overproduction of cGMP and resulting in diarrhea

cGMP, cyclic guanosine monophosphate; IL-2, interleukin-2.

such as fever, changes in white blood cell counts, disseminated intravascular coagulation, hypotension, and shock. Injection of small doses of endotoxin results in the death of most mammals. The sequence of events follows a regular pattern: (1) latent period; (2) physiological distress (diarrhea, shock); and (3) death. How soon death occurs varies according to the dose of the endotoxin, route of administration, and species of animal. In humans, LPS/LOS levels in plasma and cerebrospinal fluid are associated quantitatively with the production of inflammatory mediators, clinical symptoms, and outcome of disease. Patients with persistent septic shock, multiple organ failure, and severe coagulopathy reveal extraordinarily high levels of LPS in plasma. Mortality related to shock increases from zero to >80 percent with an increase of plasma LPS from 10 to 100 endotoxin units/ml. Although gram-positive bacteria do not produce endotoxins of this type, they can stimulate cytokine release and elicit an inflammatory response identical to that triggered by LPS. Such a response involves cell-wall polymers, such as peptidoglycan and teichoic acid.

Structure and function of LPS/LOS

The gram-negative outer membrane is a permeability barrier that excludes large molecules and hydrophobic compounds and protects the bacterial cell from detergents, such as bile salts. LPS/LOS is located on the outer surface of this membrane and presents an effective barrier to peptidoglycan-degrading enzymes, such as lysozyme, and can confer resistance to bile salts, complement, and phagocytes. As a consequence, LPS plays an important role in host–pathogen interactions. LPS consists of three components or regions, lipid A (region I), an R (rough or core) polysaccharide (region II), and an O polysaccharide (or O-antigen, region III) (Figure 3). LOS characteristically lack the O-antigen.

Region I

The lipid component of LPS/LOS, lipid A, contains the hydrophobic membrane-anchoring region. Lipid A consists of a phosphorylated *N*-acetylglucosamine (NAG) dimer with six or seven fatty acids attached. All fatty acids in lipid A are saturated. Some are attached directly to the NAG dimer, while others are esterified to 3-hydroxy fatty acids. The structure of lipid A is highly conserved among gram-negative bacteria.

Region II

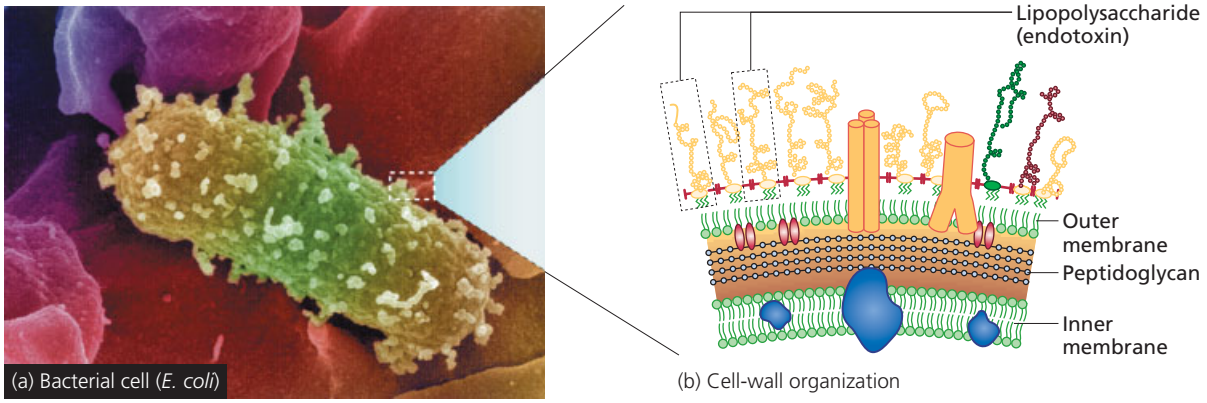
The core (R) antigen or R polysaccharide is attached to the 6 position of NAG. The R antigen consists of a short chain of sugars. For example, KDO–Hep–Hep–Glu–Gal–Glu–GluNAc. Two unusual sugars are usually present in the core region of LPS, heptose and 2-keto-3-deoxy-D-manno-oct-2-ulosonic acid (KDO). KDO is unique and invariably present in LPS and so has been an indicator in assays for endotoxins. With minor variations, the core polysaccharide is common to all members of the same bacterial genus, but it is structurally distinct from other genera. *Salmonella*, *Shigella*, and *Escherichia,* for example, have similar but not identical cores. Loss of the more proximal parts of the core, as in 'deep rough' mutants, makes the strains sensitive to a range of hydrophobic compounds, including antibiotics, detergents, bile salts, and mutagens. This region contains a large number of charged groups and is considered to be important in maintaining the permeability properties of the outer membrane. The LPS of bacteria such as *N. meningitidis, Neisseria gonorrhoeae*, and *H. influenzae* consists only of lipid A and a core polysaccharide and is often referred to as an LOS. The *N. meningitidis* LOS, for example, consists of a symmetrical hexa-acyl lipid A and a short oligosaccharide chain, which can be classified into 11 different 'immunotypes.'

Region III

The O- (or somatic) antigen or O-polysaccharide is attached to the core polysaccharide. It consists of repeating oligosaccharide subunits made up of between three and five sugars. The individual chains vary in length up to 40 repeat units. The O-antigen is much longer than the core polysaccharide, and it maintains the hydrophilic domain of the LPS molecule. Substantial variation occurs in the oligosaccharide composition between species and even between strains. At least 20 different sugars are known to be present, and many are unique dideoxyhexoses, which are found naturally only in gram-negative bacterial cell walls. Variations in the sugar content of the O-antigen contribute to the wide variety of antigenic types found in pathogens, such as *Salmonella* spp. and *E. coli*. Specific sugars, confer the immunological specificity of the O antigen and contribute to the 'smoothness' (colony morphology) of the strain. Loss of the O-specific region by mutation results in the strain acquiring a 'rough' colony morphology. Elucidation of the structural organization of LPS has relied heavily on the availability of mutants blocked in specific stages of LPS biosynthesis. Core sugars are added sequentially to lipid A followed by the O side chain, which is linked to the lipid A core polysaccharide as a preassembled unit. Mutants impaired in the assembly of lipid A usually cannot be isolated except as conditional lethal mutants, so this region is essential for cell viability and outer-membrane assembly. For example, *N. meningitidis* mutants deficient in lipid A due to mutation of *lpxA* (which encodes UDP-GlcNAc acyl transferase) require possession of a polysialic acid capsule for growth, since it can apparently substitute for the absent lipid A (Raetz and Whitfield 2002).

LPS and virulence

Lipid A (the toxic component) and the polysaccharide side chains (the nontoxic but immunogenic components) of LPS both contribute to the virulence of gram-negative



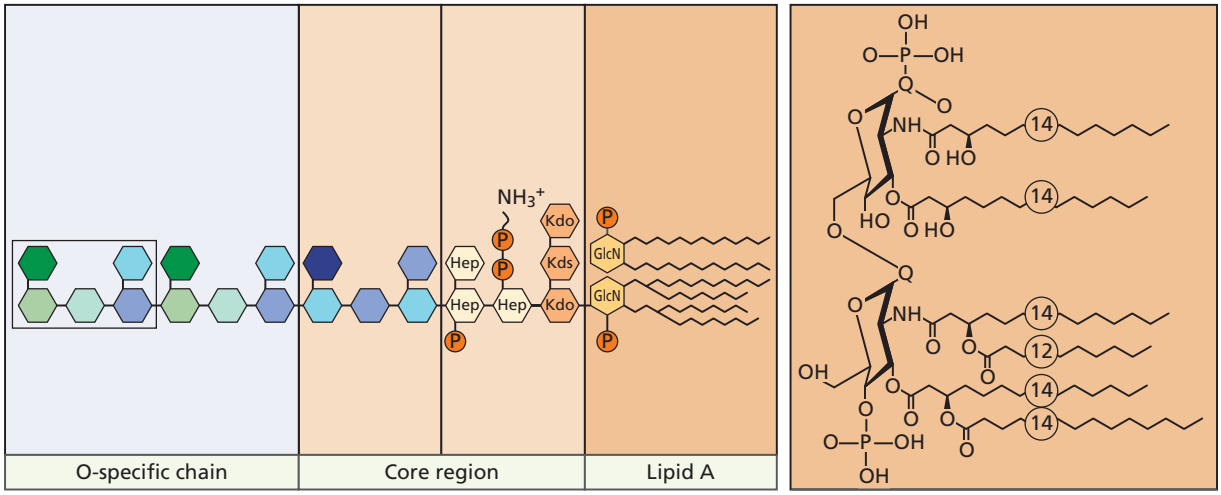


Figure 3 *The structure and localization of lipopolysaccharide (LPS). bacteria. Loss of the O-antigen increases susceptibility to complement-mediated serum killing. This is because the C5b-9 membrane attack complex (MAC) can much more readily access the bacterial cell membrane of rough rather than smooth bacteria, since in the latter the MAC forms too far from the membrane to damage the cell. Rough strains are also generally more readily phagocytosed than smooth strains. Furthermore, the O-polysaccharide is also the basis of antigenic variation among many gram-negative pathogens, including *E. coli*, *Salmonella*, *Pseudomonas*, and *Vibrio*. The existence of multiple serotypes of the same organism offers opportunities to bypass the acquired immune response to a specific serotype. However, although the O-polysaccharides are highly antigenic, they seldom elicit immune responses that confer full protection to the host against secondary challenge.

The pathophysiological effects of endotoxin are mediated via lipid A. LPS, released into the bloodstream by gram-negative bacterial cells undergoing lysis, is first bound by LPS-binding plasma proteins. These interact with CD14 receptors on monocytes and macrophages and subsequently lead to the induction of inflammation, intravascular coagulation, hemorrhage, and shock through the stimulation of cytokines including IL-1, IL-6, IL-8, TNFα, and platelet-activating factor. These in turn stimulate production of prostaglandins and leukotrienes, which are powerful mediators of inflammation and the septic shock that accompanies endotoxinemia and activate both the complement and coagulation cascades. LPS can also function as a mitogen, stimulating the polyclonal differentiation and multiplication of B cells and the secretion of immunoglobulins, such as IgG and IgM.

Genetic loci involved in LPS biosynthesis

In *E. coli*, where lipid A biosynthesis is best characterized, the genes encoding the enzymes required are scattered around the genome and on the whole are not incorporated into coregulated operons. The genes involved include *lpxABCDHKLMP*. Subsequently, an inner-membrane ABC transporter (encoded by *msbA*) functions to achieve the initial stages of lipid A export. In *Enterobacteriaceae*, the *waa* locus encodes the enzymes required for the sequential assembly of the core oligosaccharide on to the lipid A acceptor. This locus is composed of three operons: (1) the *gmhD* operon directs inner core biosynthesis; (2) the central *waaQ* operon is responsible for the outer core; and (3) the *waaA* operon contains the structural gene for a bifunctional KDO transferase, which is required for the addtion of KDO to the inner core. With few exceptions, the enzymes involved in O-polysaccharide assembly are encoded by genes at the *rfb* locus and are expressed constitutively. There are three currently known pathways for O-polysaccharide biosynthesis, which are distinguished by their respective export mechanisms: (1) dependent on the Wzy-flippase to translocate the assembled polysaccharide across the inner membrane; (2) requiring an ABC transporter to achieve this transport (a pathway confined to unbranched O-polysaccharides); or (3) reliant upon simultaneous extension of the polysaccharide and extrusion across the plasma membrane by an integral membrane synthase (Raetz and Whitfield 2002).

Protein secretion

Many virulence factors are either located on the cell surface or are secreted into the extracellular medium, e.g. adhesins, sensory receptors, and exotoxins. Bacteria have evolved a wide range of mechanisms to translocate proteins across their membranes. It has been estimated that approximately 20 percent of the polypeptides synthesized by a bacterium are destined for a location external to the cytoplasmic membrane, and those in the outer membrane or beyond will be exposed to the host environment.

In gram-negative bacteria, there are three mechanisms for inner membrane translocation: the Sec machinery, the SRP-dependent machinery, and the Tat machinery. The Sec machinery is the most intensively studied, and polypeptides destined for it bear an N-teminal targeting signal, which is cleaved by a peptidase on the periplasmic face of the inner membrane. During Sec-dependent translocation the unfolded polypeptide chain is threaded through a channel (translocon) composed of SecYEG and a number of associated proteins (SecD, SecF, YajC, YidC) powered via SecA by the hydrolysis of ATP (Economou 2002; van Wely et al. 2001). Signal peptide binding to SecA is followed by ATP binding, which induces a profound conformational change in SecA, enabling it to interact with the translocon. ATP is hydrolyzed, reversing the conformational change and directing the release of the polypeptide. Binding of another ATP molecule enables SecA to bind to the polypeptide again, but this time 2.5 kDa nearer its C-terminus. This cycle is repeated many times, shunting the polypeptide through the channel. Some Sec-dependent proteins interact with the cytoplasmic chaperone SecB prior to translocation; others (particularly multiple-membrane-spanning membrane proteins) are recognized by SRP (Economou 1999). The Tat mechanism differs from those described above, since it affects the translocation of folded polypeptides that contain bound cofactors (Palmer and Berks 2003). In common with the Sec and SRP pathways, the Tat system requires an N-terminal targeting signal peptide; however, it differs by the inclusion of two arginines (hence the name twin arginine translocation (TAT)). Beyond this, no specific amino acid consensus has been attributed to signal peptides of any of these mechanisms apart from a general structure composing of a hydrophobic region flanked by a positively charged N-terminal segment and a basic C-terminal sequence contained within an approximately 20 amino acid stretch culminating in the peptidase cleavage site (Pugsley 1993).

Proteins destined for the inner membrane fold within it (Pugsley 1993), whereas those residing in the periplasm are aided in their folding by local chaperones. Outer membrane proteins frequently possess a C-terminal phenylalanine (de Cock et al. 1997), and their localization is usually assisted by periplasmic proteins, e.g. Skp (Buileris et al. 2003; Missiakas et al. 1996). Recently, a highly conserved protein required for outer-membrane protein assembly was shown to be essential in *N. meningitidis* and is likely to play a central role in this process (Voulhoux et al. 2003). In the case of lipoproteins, localization can be achieved by dedicated piloting proteins. Attachment of a lipid is signalled by an LXXC motif contained within the signal peptide adjacent to the peptidase cleavage site. Cleavage results in an N-terminal cysteine residue that is acylated. Inner and outer membrane lipoproteins are then distinguished by the second amino acid of the mature protein. If the second amino acid is not an aspartate, the lipoprotein is recognized by LolCDE and localized on the periplasmic face of the outer membrane (Masuda et al. 2002). LolCDE is an ABC transporter that releases the lipoprotein from the inner membrane, whereupon it interacts with LolA. The LolA–lipoprotein complex crosses the periplasm and interacts with the outer-membrane receptor LolB, which is essential for outer-membrane anchorage (Fukuda et al. 2002).

To secrete proteins across both the inner and outer membrane, gram-negative bacteria utilize one of five main pathways (Figure 4). The type I mechanism

(see Table 4) is well known for its direction of the secretion of the hemolytic toxin HlyA from *E. coli*. This process proceeds in a single step from the cytoplasm using just three proteins. In the inner membrane are the HlyB and HlyD proteins. HlyB contains an ATPase activity and resembles the multidrug resistance protein of eukaryotes. In the outer membrane, and spanning the periplasm, is TolC, which docks into the membrane fusion protein (HlyB) forming a proteinaceous channel through which the unfolded HlyA polypeptide can move directed by its C-terminal targeting signal, which remains uncleaved throughout (Thanassi and Hultgren 2000; Andersen et al. 2001).

Type II secretion (general secretory pathway (GSP)) utilizes two steps. First, proteins use either Sec or Tat to enter the periplasm; then, approximately 14 dedicated GSP proteins form the machinery required to secrete the fully folded protein across the outer membrane. This pathway is used by many bacteria to secrete virulence factors (see Table 5), such as the multisubunit cholera toxin. The targeting signal for the GSP is currently not known, and the machinery is composed of a number of

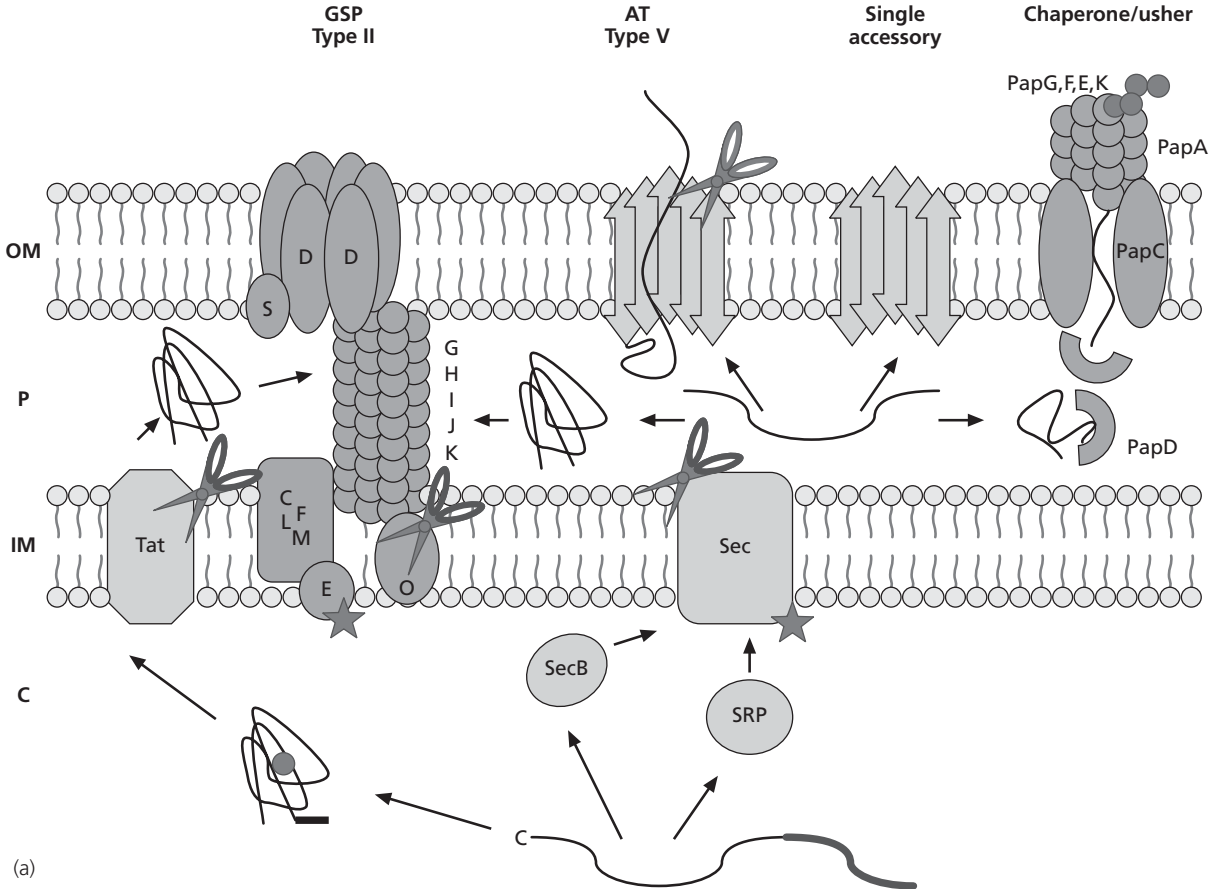

Figure 4 *Schematic representation of bacterial protein secretion machineries.* **(a)** *Depicts those pathways with a distinct step for translocation across the inner membrane. Polypeptides synthesized in the cytoplasm with an N-terminal signal peptide interact with either SecB or SRP and are targeted to the Sec machinery, which translocates them across the cytoplasmic membrane and concomitantly cleaves their signal peptide (as indicated by the scissors). This translocation occurs by threading the unfolded polypeptide across via the action of SecA and is driven by ATP hydrolysis (as indicated by the star). A subset of proteins with an N-terminal signal peptide frequently bearing twin arginines fold around their cofactors and are translocated through the Tat machinery. From the periplasm, a variety of pathways exist to achieve outer-membrane secretion. (1) Autotransported proteins (AT) insert their C-terminal β-barrel domain into the outer membrane to create a channel through which the rest of the polypeptide is threaded. This channel may be formed from multimers or involve Omp85. Cleavage at the cell surface liberates the mature protein, leaving the β-barrel domain attached to the cell. This pathway is also refered to as type V. (2) A similar mechanism is employed by ShlA. However, rather than being contained within a single polypeptide, the transporter domain is a separate protein and thus cleavage is not required (single accessory pathway). (3) Subunits of type IV pili interact with the PapD chaperone, which delivers them to the PapC usher, which in turn directs assembly of the pilus (chaperone/usher pathway). (4) Following folding, some proteins are exported by the general secretory pathway (GSP or type II). This requires 12 or more proteins; the system employed by pullulanase, which is secreted by* Klebsiella oxytoca, *is shown here. The single integral outer-membrane component (GspD) is piloted to its position by the lipoprotein (GspS), together these proteins form a gated channel through which the folded proteins are secreted. This complex is proposed to be linked to the inner-membrane components (GspC, E, F, L, M) by a pilus-like structure composed of GspG, H, I, J, K. The latter are processed by the methylating protease, GspO. GspE is likely to hydrolyze adenosine triphosphate (ATP) and contribute to energizing the system.*

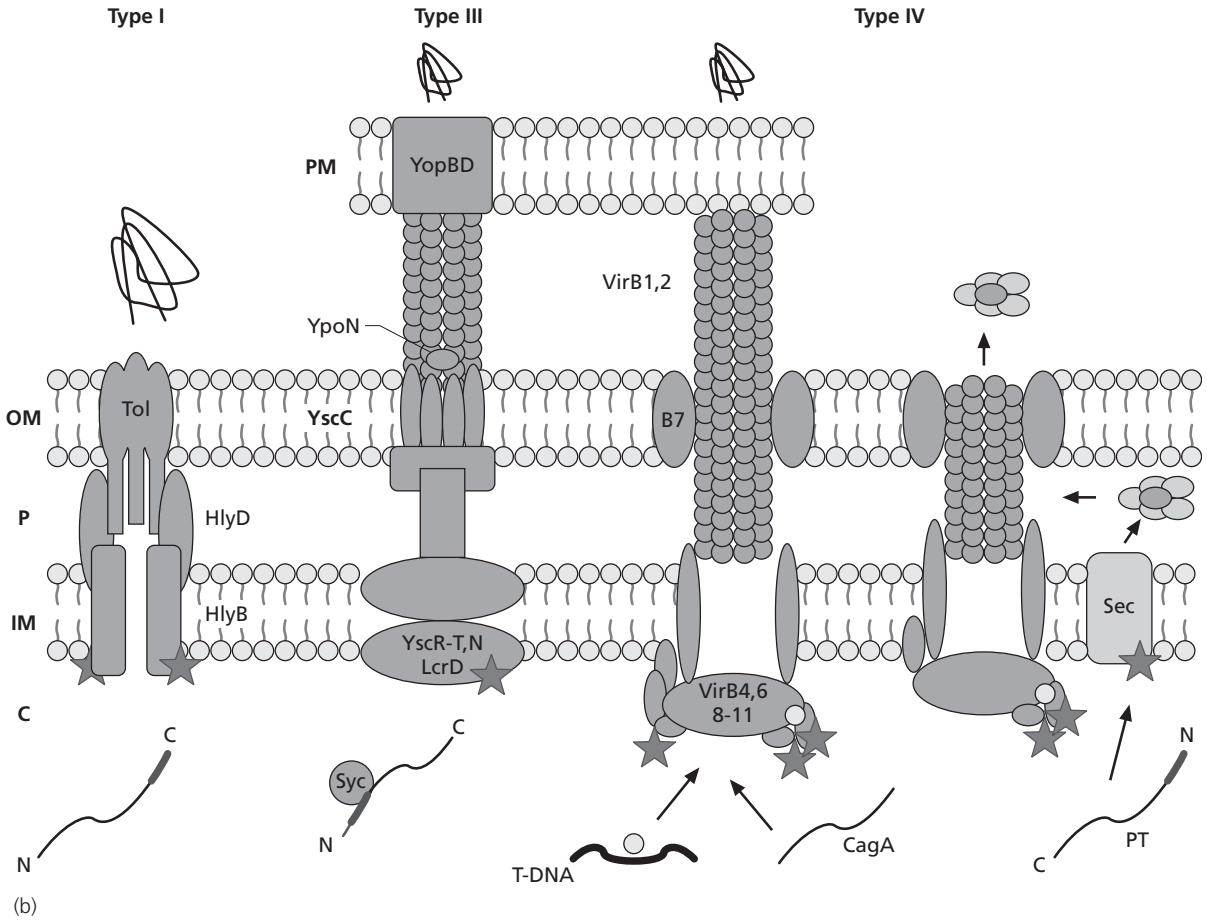

Figure 4 *Schematic representation of bacterial protein secretion machineries (Continued)* **(b)** *A representation of the complex machineries that comprise the type I, III, and IV pathways. Type I-dependent proteins (see Table 5) bear a C-terminal targeting peptide that is not cleaved during translocation of the unfolded polypeptide out of the cell in a single step, which avoids the periplasm. Secretion of the archetypical type I-dependent protein (HlyA from* Escherichia coli*) is achieved through a channel composed of the ATP binding dimer of HlyB, the membrane fusion protein (HlyB), and the outer-membrane protein TolC. The type III machinery uses a needle-like structure that resembles a flagellum to inject proteins directly into eukaryotic cells, and as shown here is used by Yops, which are secreted by* Y. enterocolitica*. Some type III substrates contain two N-terminal signals for targeting, one encoded by the mRNA, and the second by amino acids to which the cytoplasmic Syc chaperones bind. YscR-U and LcrD may form a central secretion apparatus energized by YscN-dependent ATP hydrolysis. The YsdC outer-membrane component resembles the GspD secretin, and the surface-located YopN is thought to act as a channel gate. Translocation of Yops into the target eukaryotic cell may occur via a channel formed in the plasma membrane by YopD and YopD. The type IV secretion pathway can function in alternative ways, depending on the bacterial host. Like the type III pathway, it can achieve direct injection of proteins (e.g. CagA, VirE2) or protein-bound DNA (T-DNA) into eukaryotic cells. Alternatively, proteins that have reached the periplasm via the Sec machinery can assemble and enter the type IV pathway to achieve extracellular localization (pertussis toxin (PT)). The machinery comprises multiple ATPases (VirB4, VirB11) and other inner-membrane structural components (VirB6, VirB8, VirB9, VirB10) plus an outer-membrane component (VirB7) that are linked together by a pilus-like structure composed of VirB1 and VirB2. The relative positions of the bacterial cytoplasm (C), inner membrane (IM), periplasm (P), outer membrane (OM), and the eukaryotic plasma membrane (PM) are indicated.*

inner membrane components, including an ATPase and a set of proteins that resemble pilin subunits (the pseudopilins) and that are proposed to form a retractable pilus, which pushes proteins through the outer membrane pore. The outer-membrane channel is formed by a multimer of a single protein (the GspD secretin) and is likely to be tightly gated (Thanassi and Hultgren 2000).

The type III secretion machinery achieves injection of proteins (see Table 6) with the aid of upwards of 14 components directly into eukaryotic cells (see below), as does the type IV machinery (TFSS). A TFSS is possessed by several pathogens of plants and animals (see Table 7), where the secretion machinery transfers protein substrates intercellularly and appears to be related ancestrally to conjugation systems that have evolved the additional capacity to translocate DNA–protein complexes.

The TFSS machinery comprises 12 components that span the periplasm and membranes through the formation of a pilus, which takes differing forms in different organisms and can directly attach to the eukaryotic

Table 4 *Examples of proteins secreted by type I machinery*

Bacterium	Type I secreted proteins
Escherichia coli	Hemolysin (HlyA)
Serratia marcescens	Metalloprotease

Pasteurella haemolytica	Leukotoxin
Bordetella pertussis	Cyclolysin
Pseudomonas aeruginosa	Metalloprotease
Rhizobium leguminosarum	NodO

target cell (Figure 4) (Christie 2001). The components can be divided into distinct activities: (1) substrate processing (the relaxosome); (2) substrate docking (coupling proteins/chaperones); (3) translocation (channel); and (4) cell–cell attachment (pilus/adhesions). The relaxosome function is not required for those TFSSs that do not transfer DNA since it functions to cleave the DNA strand destined for transfer at the plasmid origin of transfer. The relaxase remains attached to the DNA and may serve to pilot it for translocation. Coupling proteins and chaperones appear necessary for presentation of DNA and also proteins for translocation, and most contain Walker A and B nucleotide-binding motifs suggestive of ATPase activity (the TraG homologues). Other putative ATPases contributing to the function of TFSSs are (1) those showing homology to VirB4, which are proposed to transduce information in the form of ATP-induced conformational changes, across the cytoplasmic membrane to the extracytoplasmic subunits (Dang et al. 1999); and (2) those that form oligomeric structures in the cytoplasm, which are reminiscent of the GroEL family (homologs of VirB11), although it is unclear whether they function for substrate translocation or biogenesis of the translocase. It should be noted that the multisubunit pertussis toxin of *Bordetella pertussis* uses the GSP (Figure 4) to enter the periplasm and, following assembly, is secreted across the outer membrane via the TFSS in contrast to other effectors released via a TFSS, which enter the machinery from the bacterial cytoplasm (Thanassi and Hultgren 2000; Christie 2001).

In common with the type I secretion pathway, the type III secretion process is Sec-independent; proteins

secreted by it do not accumulate in the periplasm, and nor are they subjected to N-terminal processing. However, the protein signal sequence for type III secretion is considered to reside within the N-terminal of the secreted proteins, since this region appears necessary for secretion and can direct the secretion of hybrid fusion proteins. Exhaustive mutational analysis has revealed a high degree of tolerance for sequence changes within the N-terminus of some secreted proteins, without loss of secretion. Moreover, the N-terminal sequences of proteins secreted via the type III pathway share no recognizable structural similarities that may constitute a common secretion signal. Therefore, it has recently been proposed that the secretion signal may actually reside in the 5′ region of the mRNA that encodes the secreted proteins (Anderson and Schneewind 1997).

The process of protein secretion via this system requires the involvement of small cytoplasmic proteins termed chaperones, which protect the secreted proteins from premature interaction with components of the secretion machinery. Apart from a cytoplasmic, membrane-associated ATPase, and an outer-membrane

component that is homologous to the secretin of the type II secretion pathway, most of the components are located in the inner membrane. Interestingly, many of the components of the type III secretion apparatus show homology with those of flagella. In accordance with this, some type III secretion systems assemble supermolecular structures on the bacterial surface (Ginocchio et al. 1994). In contrast to type I secretion, where the secreted enzymes are active in the extracellular space, type III secretion systems appear to be dedicated to the translocation of pathogenicity proteins directly into the cytosol of eukaryotic cells and in some cases appear to be regulated by contact with the surface of the target eukaryotic cell (Charkowski et al. 1997). Type III secretion systems contribute to the virulence of diverse gram-negative pathogens (Table 6). Many of the type III secreted proteins interact directly with host cell components to alter host cell signal transduction, once inside the eukaryotic cytosol (see Subversion of host cell signal transduction).

The type V machinery is perhaps the simplest, since secretion appears to be determined within the primary sequence of the secreted protein, and hence it is often described as autotransportation. This is described later in Evolution of pathogens within the host; however, variations exist whereby the outer-membrane transporter domain is separated from the transported protein (e.g. the hemolysin secreted by *Serratia marcescens*) (Yang and Braun 2000). Finally, another terminal branch of the GSP exists, which is utilized for the formation of Pap pili. This pathway is referred to as the chaperone/usher pathway and involves the interaction of pilus subunits with the PapD periplasmic chaperone, which facilitates their proper folding whilst preventing premature aggregation and guiding them to the PapC usher in the outer membrane, whereupon they assemble into a pilus (Stathopoulos et al. 2000; Thanassi et al. 1998).

Subversion of host cell signal transduction

Many of the proteins injected directly into eukaryotic cells by the type III secretion pathway interfere with signal transduction. For example, through YopH-mediated dephosphorylation of several macrophage proteins whose transient tyrosine phophorylation is required for normal phagocytosis, pathogenic *Yersinia* spp. resist the host's primary immune defenses by preventing their uptake into professional phagocytes. Other effectors are also injected into eukaryotic cells by *Yersinia* spp. and contribute to their cytotoxicity, e.g. by altering the cytoskeleton. In contrast to pathogenic *Yersinia* spp., *Shigella* spp. occupy predominantly intracellular locations, and although the pathogenic strategies and disease caused by these organisms differ entirely, both pathogens use type III secretion systems as a key virulence mechanism. In vivo invasiveness, as well as the induction of membrane ruffles on cultured epithelial cells, depends on the *Shigella* type III secretion system, which delivers four proteins (IpaA, IpaB, IpaC, and IpaD) into eukaryotic cells. Together, these cause protein tyrosine phosphorylation of a number of cytoskeletal proteins, leading to the localized accumulation of a variety of cytoskeletal (F-actin, -vinculin, and -actinin) and signal transduction molecules (the protein tyrosine kinase $pp60^{c\text{-}src}$ and the GTP-binding protein rho) at the site of bacterial attachment. This results in tyrosine phosphorylation of paxillin, cortactin, and the focal adhesion kinase $pp125^{FAK}$. Shortly after internalization, the bacteria lyse the phagocytic membrane and gain access to the cytoplasm and, in macrophages, induce apoptosis. In addition, attraction of neutrophils to the site of bacterial infection occurs (Hueck 1998). Interestingly, salmonellae contain two type III secretion systems, which are encoded by two distinct gene clusters termed SPI-1 and SPI-2 (for *Salmonella* pathogenicity island). These two type III secretion systems appear to play different roles during pathogenesis, with SPI-1 being required for initial penetration of the intestinal mucosa and SPI-2 being necessary for subsequent systemic stages of infection. The effectors delivered by SPI-1 (SopE, SopE2, SopB, SipA, SipC, SptP) induce reversible actin cytoskeletal rearrangements by stimulating the host signal transduction and directing modulation of actin dynamics (Zhou and Galán 2001). The effectors translocated by SPI-2 interfere with vesicular trafficking allowing survival within the eukaryotic cell (see Infiltration of host tissues) (Fang and Vazquez-Torres 2002). The opportunistic pathogen *P. aeruginosa* also employs type III secreted proteins to inflict epithelial cell damage and affect dissemination within infected hosts. Although their precise contribution to pathogenesis is unclear, two exotoxins with ADP-ribosyltransferase activity (exoenzyme S, ExoS; exoenzyme T, ExoT) secreted via a type III secretion pathway by *P. aeruginosa* target members of the H-Ras and K-Ras family of GTP-binding proteins and vimentin (an intermediate filament protein) (Hueck 1998).

Another example of a bacterium that effectively subverts eukaryotic cell signaling is enteropathogenic *E. coli* (EPEC). EPEC belong to a growing family of diarrheagenic *E. coli* strains that cause a characteristic attaching and effacing lesion on infected small-intestine enterocytes and cells grown in culture. This lesion consists of gross cytoskeletal damage to the brush-border microvilli, the deposition of filamentous actin beneath attached EPEC, and the formation of pedestal-like structures. In addition, many classical *EPEC* strains are characterized by their clustered or localized pattern of adherence to epithelial cells, which results in the formation of microcolonies on the cell surface. Intimate attachment, effacing of microvilli, and formation of

pedestals require a bacterial adhesin (called intimin) and EPEC type III secretion. Although intimin is not secreted by the type III secretion pathway, the encoding gene (*eaeA*) is located within the gene cluster that encodes the EPEC type III secretion system, and intimin functions synergistically with type III secretion in pedestal and A/E lesion formation. Intimin specifically binds to translocated intimin receptor (Tir), which is secreted by the type III secretion apparatus. Three other type III secreted proteins, EspA, EspB, and EspD, are required for membrane insertion of Tir. Concomitant with pedestal formation, adherent EPEC strains induce tyrosine phosphorylation of several proteins in the eukaryotic cell, including Tir and phospholipase C-1. While Tir phosphorylation has been thought to facilitate intimin binding, activation of phospholipase C-1 induces inositol triphosphate and Ca^{2+} fluxes, which might be involved in the cytoskeletal rearrangements involved in pedestal formation. Another protein secreted by the type III machinery of EPEC is the mitochondrial associated protein (Map), which targets the mitochondria and disrupts their membrane potential. In addition, via activation of the host GTPase (Cdc42), Map stimulates nonpedestral-related cytoskeletal rearrangement, e.g. filopodia formation (Hueck 1998; Kenny 2002; Vallance and Finlay 2000; Campellone and Leong 2003) (Figure 5).

BACTERIAL SENSORY NETWORKS

Microorganisms inhabit diverse ecological niches where survival will depend on their capacity to sense the local environmental conditions and adapt by regulating the expression of specific genes and operons. Consequently, bacteria have developed multiple, highly sophisticated mechanisms to gather, process, and transduce environmental information, such as pH, temperature, nutrient availability, osmolarity, and cell population density. Pathogenic bacteria are therefore likely to encounter countless different environmental situations as they move through the host or between the host and external environment, and need to continually monitor diverse physical and chemical signals and integrate their responses. Such sensory transduction mechanisms operate at the transcriptional, post-transcriptional, and translational levels and bacteria employ multiple interconnected regulatory circuits to coordinate their responses. The 6.3-MB genome of *P. aeruginosa*, for example, contains around 5 500 genes, some 10 percent of which encode regulatory proteins. These enable the bacterium to express or repress genes as the conditions dictate. For example, if iron is plentiful, the energetically expensive synthesis of siderophores and their associated export and import pathways can be switched off. For bacteria such as *V. cholerae*, switching between an aquatic lifestyle and that required for survival within a human host has highlighted an inverse correlation between motility and virulence gene expression.

Pathogenic bacteria will therefore employ many different signal transduction mechanisms, some of which are required for 'house-keeping,' since they are required for replication, cell division, and the maintenance of cell viability. Others control the synthesis of the colonization factors, toxins, and tissue-degrading enzymes that characterize the organism as a pathogen and that may be required only in certain host compartments.

Given the multistage adaptive process leading to the establishment of infection, bacteria require multiple virulence factors that can be deployed at the appropriate time and place. For example, during the early stages of infection, bacteria express cell-surface adhesins to facilitate attachment to eukaryotic cell surfaces and extracellular matrices. If the infection becomes systemic, the expression of exotoxins and host-avoidance factors is upregulated, with the concomitant downregulation of colonization factors. This is important because virulence factors that contribute to infection in one host compartment may render the pathogen susceptible to host defenses in another. In this section, three main sensory pathways will be considered: iron-dependent repression, two-component signal transduction, and quorum sensing. Although treated as separate environmental parameters, it is important to understand that each is merely one parameter amongst many that a bacterial cell must integrate in order to determine subsequent behavior (Figure 6) (Withers et al. 2001).

Iron-dependent repression

To grow in vivo, bacterial pathogens deploy high-affinity iron-scavenging systems, which depend on either siderophores or surface receptors for host iron and heme-containing proteins (see Iron scavenging). The genes involved in the biosynthesis of siderophores and their transport in and out of the bacterial cell, as well as those encoding for surface receptors, are coordinately negatively regulated in response to the cellular iron status. This is because they are energetically expensive systems that confer an advantage for the bacterium only in environments where iron is not readily available. In *E. coli,* the 17-kDa Fur repressor protein controls transcription from iron-responsive promoters in an iron-dependent manner, i.e. to be active, Fur requires ferrous iron as a corepressor. When iron is plentiful, the Fur–Fe^{2+} complex interacts with an operator sequence called the *fur* box and prevents gene expression. During iron starvation, Fur is stripped of iron by the cell and is no longer able to function as a repressor, thus permitting expression of the iron-repressed structural genes. Homologs of Fur have been described in many different gram-negative pathogens including *Yersinia pestis*, *V. cholerae*,

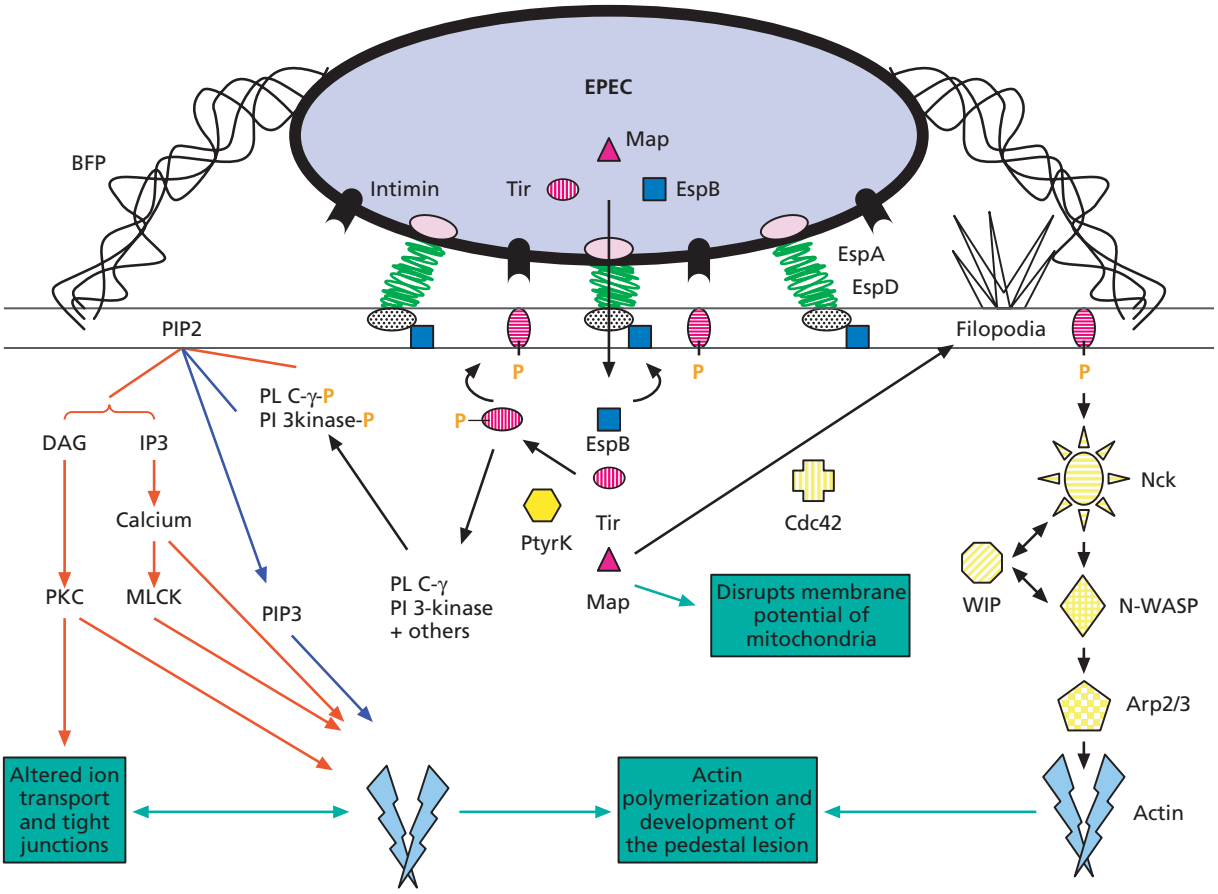

Figure 5 *Subversion of eukaryotic cell signaling cascades by enteropathogenic* Escherichia coli *(EPEC). Bundle-forming pili (BFP) allow initial aderence of EPEC to the eukaryotic cell surface. The type III secretion syringe composed of EspA (green wavy lines) allows injection of EspB (blue square) and EspD (black chequered oval), which form the translocon in the plasma membrane. Other injected proteins include Map (pink triangle) and Tir (red and white striped oval). Map, by direct or indirect mechanisms, activates the small GTPase protein Cdc42, converting it to its GTP-bound membrane-associating form that drives actin polymerization and filopodia formation. It is postulated that Cdc42 activation also leads to the modulation of other undefined cellular processes, again by direct and/or indirect mechanisms. Map is also targeted to mitochondria, where it disrupts their membrane potential. Concurrently, Tir is proposed to undergo host- (PtyrK) and bacteria-dependent modification, leading to its insertion into the plasma membrane. The fully modified membrane-inserted Tir molecule interacts with intimin to trigger signaling events, leading to pedestal formation and other signaling events, such as phosphorylation of phospholipase C (PLC-1) and phosphoinositol 3 kinase (PI3-kinase). Changes in inositol phosphate fluxes lead to calcium release, which may in turn affect actin polymerization. Membrane-embedded tyrosine-phosphorylated Tir binds the adaptor protein Nick, which recruits N-WASP or WIP–N-WASP, complex to trigger activation of Arp2/3 complexes. This leads to actin assembly and pedestal formation with Nick, WIP, N-WASP, and Aro2/3 in its tip, myosin II and tropomyosin in the base, and F-actin, α-actinin, Talin, Exrin, and Villin distributed throughout. DAG, diacylglycerol; MLCK, myosin-like chain kinase; PKC, protein kinase C. See also Kenny (2002) Campellone and Leong (2003), Vallance and Finlay (2000), and www.biotech.ubc.ca/faculty/finlay/EPEC.htm for animations and further illustrations.*

P. aeruginosa, *N. meningitidis*, and *H. influenzae*. In addition to regulating genes associated with iron acquisition, Fur also regulates expression of superoxide dismutases and exotoxins, such as shiga toxin, hemolysin, and exotoxin A. Gram-positive pathogens such as *Corynebacterium diphtheriae*, *M. tuberculosis*, and the staphylococci also possess iron-responsive regulatory proteins related to Fur. In *C. diphtheriae*, for example, DtxR regulates production of siderophores, a heme oxygenase (which enables the organism to strip the ferric iron from heme) as well as diphtheria toxin synthesis. Thus, in addition to regulating high-affinity iron-transport mechanisms, iron-dependent repressors also regulate the expression of virulence genes unrelated to iron metabolism. However, defining their contribution to pathogenicity is not straightforward, since the constitutive expression of target structural genes may either enhance or reduce the fitness of the pathogen. For example, the *S. enterica* serovar Typhimurium *fur* mutant remains virulent in an experimental animal infection model, while many *E. coli* enteropathogens exhibit attenuated virulence when *fur* is inactivated. In other pathogens, e.g. *P. aeruginosa*, attempts to mutate the *fur* gene have not been successful, indicating that in these bacteria, Fur fulfils an essential function (Hantke 2001).

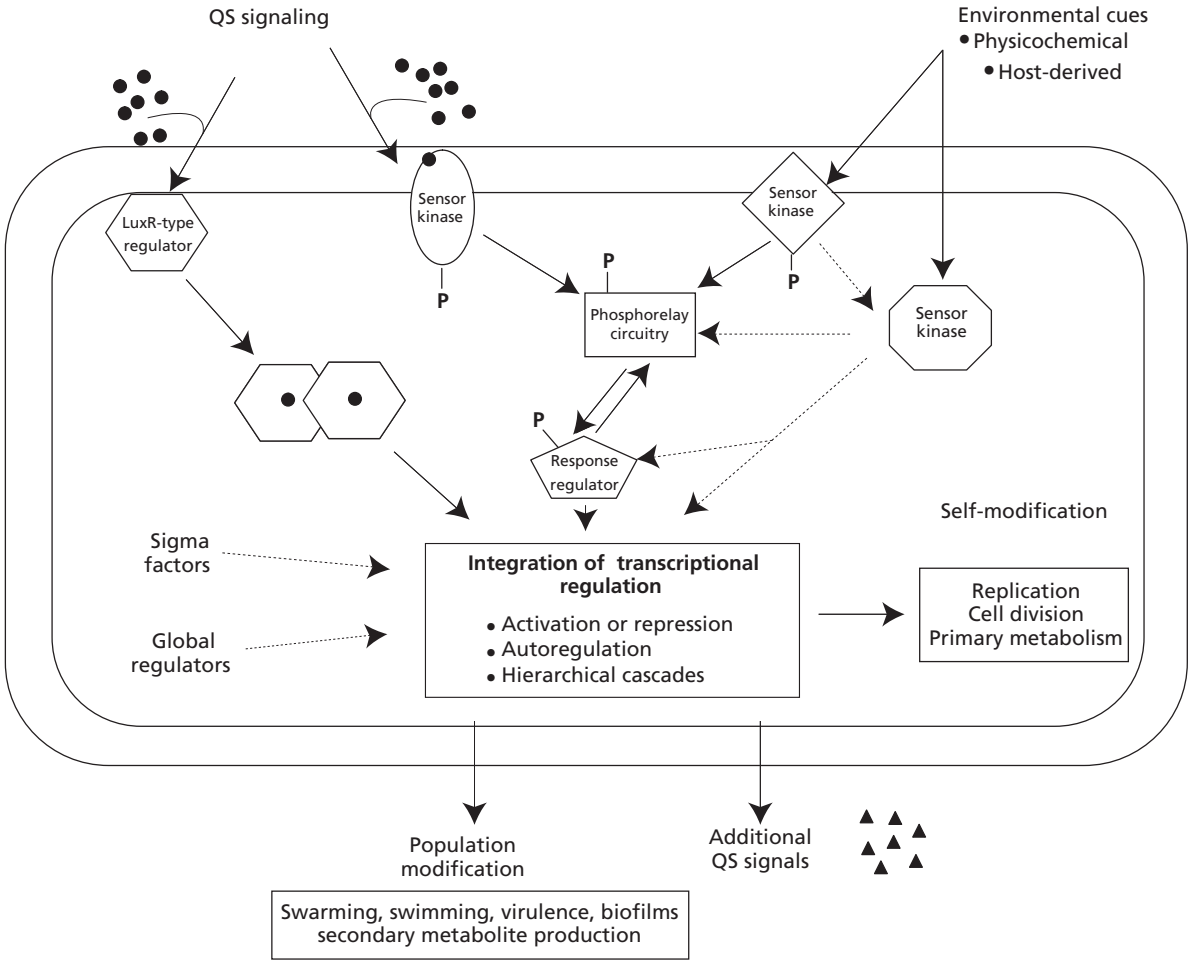

Figure 6 *Integration of quorum-sensing and environmental signals. Quorum sensing is one parameter amongst many that the cell integrates in order to determine subsequent behavior. Quorum-sensing signal molecules and environmental signals are internalized or detected at the cell envelope and initiate signal transduction, leading to gene expression changes. This diverse array of signaling cascades may act in parallel or be organized in a hierarchical manner to create a 'neural' regulatory network. Amended from Withers et al. (2001).*

Two-component signal transduction systems

Bacterial two-component signal transduction systems (TCSTS) are ubiquitous throughout the bacterial kingdom, are abundant within individual bacterial genomes, and have been adapted to regulate an enormous number of genes, including many virulence determinants (Table 8) (Stephenson and Hoch 2002; Dziejman and Mekalanos 1994; Hoch and Silhavy 1995). They consist of two regulatory proteins, a cytoplasmic membrane-associated sensor that samples the environment for a specific signal and a response regulator that mediates the internal response of the bacterial cell. Sensor and response regulator proteins exchange information by transferring a phosphate group from the sensor to the response regulator through conserved domains within the two proteins (Figure 7). In classical TCSTS, perception of an external signal results in the phosphorylation of a histidine in the sensor (a histidine protein kinase). The phosphate group is subsequently transferred to a conserved aspartate within the receiver domain of the response regulator. Most response regulators are transcriptional activators or repressors (or both) that consist of two domains, an N-terminal receiver domain and a C-terminal DNA-binding domain.

TCSTS sense a variety of different factors including oxygen (Aer, *E. coli*), hydrogen (Hox, *Ralstonia eutropa*), quorum-sensing signal molecules (e.g. LuxQO, *V. cholerae*), Mg^{2+} (e.g. PhoPQ, *Salmonella*), and phosphate limitation (e.g. PhoBR, *E. coli*; PhoPR, *Bacillus subtilis*). The number of TCSTS produced by a particular bacterium appears to reflect the range of different environments it encounters during its lifecycle. For example, *H. pylori*, which uniquely inhabits the human stomach, has only three TCSTS pairs, whilst *P. aeruginosa*, which is found in a multitude of different environments, has an extraordinary number of putative two-

component regulators, with 55 sensor proteins, 89 response regulators, and 14 sensor/response regulator hybrids (www.pseudomonas.com/suppdata.asp). The role performed by TCSTS also varies; for example, only three of the 16 TCSTS pairs contained within the genome of *S. aureus* appear to be essential (Throup et al. 2001). TCSTS can perform defined roles, e.g. LuxQO regulates the production of bioluminescence by *Vibrio harveyi*, or they can have a wide-ranging effect, e.g. the PhoPQ system of *Salmonella* governs the expression of at least 40 proteins including: (1) those mediating adaptation to Mg^{2+}-limiting environments; (2) virulence factors; and (3) components of the bacterial cell envelope. Indeed, *Salmonella* strains harboring null alleles of the *phoP* or *phoQ* gene are highly attenuated for virulence. This may be due to an inability to determine that cells have attained a subcellular location through the monitoring of the environmental Mg^{2+} concentration, although PhoPQ can control virulence even in pathogens that do not have an intracellular lifestyle (Groisman 2001).

The BvgAS TCSTS is another example of one that has a major influence on virulence since it controls the expression of nearly all the known virulence genes in bordetella that cause respiratory infections in mammals. BvgAS functions like a molecular switch, mediating a biphasic transition between the Bvg^+ and Bvg^- phases in response to environmental cues, which are currently unknown. The Bvg^+ phase is necessary and sufficient for respiratory infection by *Bordetella bronchiseptica*, whilst the Bvg^- phase is adapted for survival under conditions of extreme nutrient deprivation (Stockbauer et al. 2001).

E. coli contains 36 TCSTS and among these are those that mediate chemotaxis, which are typically transmembrane homodimers composed of an external ligand-binding domain to monitor attractant compounds (such as serine or aspartate), four transmembrane helices, and internal methyl-accepting and signaling domains. These

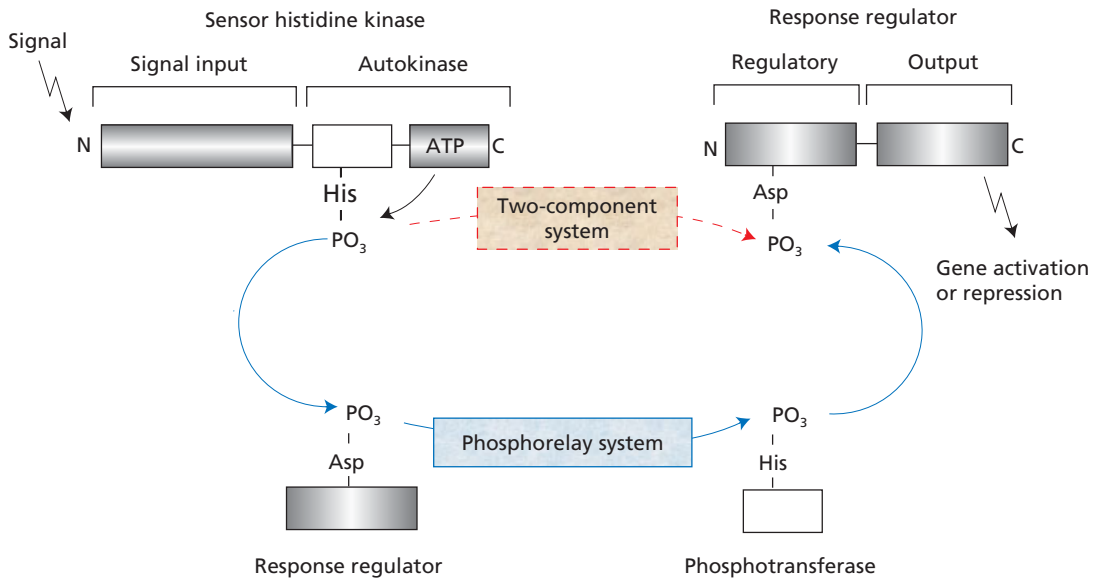

Figure 7 *Cartoon demonstrating the mechanism of two-component signal and phosphorelay signal-transduction systems. Signal ligands stimulate autophosphorylation of the sensor kinase on a histidine residue. In a two-component system (red), the phosphoryl group is subsequently transferred to an aspartate residue of a two-domain response regulator to activate its transcriptional properties. In a phosphorelay (blue), the phosphoryl group is first transferred to an aspartate of a single-domain response regulator that lacks a DNA-binding domain, and then to a histidine residue of a phosphotransferase that subsequently serves as the phosphoryl donor to activate the transcriptional properties of the response regulator. Redrawn from Stephenson and Hoch 2002.*

chemoreceptors (methyl-accepting chemotaxis proteins (MCP)) form higher order aggregates with other signaling proteins at the cell poles and control the phosphorylation state of the histidine protein kinase, CheA, via the linker, CheW, and the two response regulators, CheY and CheB. Phospho-CheY binds to FliM in the flagellar motor to augment clockwise rotation (Armitage et al. 2003; Parkinson 2003).

A family of proteins distinct from TCSTS, but also involved in signal transduction, are the hybrid sensor-regulators related to ToxR and TcpP, which regulate the genes encoding CT and TCP (see Examples of bacterial adhesins and their receptors) of *V. cholerae*. These unusual transcription regulators are localized to the cytoplasmic membrane and also regulate gene expression by binding to DNA and activating transcription. They share a bitopic arrangement with a cytoplasmic amino terminus and a periplasmic carboxy-terminus separated by a short transmembrane stretch of hydrophobic amino acids, and often work in conjunction with an effector protein that is localized on the periplasmic face of the inner membrane, e.g. ToxR interacts with ToxS and TcpP with TcpH. The cytoplasmic DNA-binding domains of ToxR and TcpP bear homology with the transcriptional regulator OmpR and consist of a helix–turn–helix (HTH) domain and two β-strands separated by a loop. Interaction of the loop between the two helices of the HTH domain with the carboxy-terminal portion of the α-subunit of RNA polymerase activates transcription. ToxR and TcpP act together to regulate CT and TCP expression via activation of the *toxT* gene. It should be noted that other factors also influence the production of CT and TCP and that ToxR and TcpP can also regulate other genes in *V. cholerae*, e.g. biofilm formation (Crawford et al. 2003).

Quorum sensing: bacterial cell-to-cell communication

A crucial feature of many bacterial infections is a requirement for the pathogen to attain a cell population density sufficient to overcome host defenses and establish an infection. A mechanism for coordinating the control of multiple virulence genes as a function of population density offers a survival advantage to the pathogen, such that the host is overwhelmed before a defense response can be initiated fully. In this context, the ability of bacterial cells to communicate with each other offers the pathogen a survival advantage by orchestrating collective attack against the host immune system.

Many different gram-negative and gram-positive pathogens are now known to communicate using specific extracellular signal molecules, which facilitate the coordination of virulence and survival gene expression. The term ‘quorum sensing’ is commonly used to describe the phenomenon whereby the accumulation of a diffusible, low-molecular-weight signal molecule (sometimes called an ‘autoinducer’) enables individual bacterial cells to sense when the minimal number, or ‘quorum,’ of bacteria has been achieved for a concerted response to

be initiated (for reviews see Swift et al. 2001; Camara et al. 2002; Williams et al. 2000). The accumulation of a diffusible signal molecule also indicates the presence of a diffusion barrier, which ensures that more molecules are produced than lost from a microhabitat (Winzer et al. 2002b; Redfield 2002). This could be regarded as a type of 'compartment sensing,' where signal molecule accumulation is both the measure for the degree of compartmentalization and the means to distribute this information among the entire population. Similarly, diffusion of quorum-sensing signal molecules between spatially separated bacterial subpopulations may convey information about their physiological state, their numbers, and the individual environmental conditions encountered.

Bacteria employ a number of different quorum sensing 'languages,' and several families of signal molecules have been characterized. These range from post-translationally modified peptides to quinolones, lactones, and furanones (Williams 2002). In addition, siderophores (see Iron-dependent repression), which previously were considered only in the context of iron transport, may also function in the producer organism as signal molecules capable of controlling genes unrelated to iron acquisition (Lamont et al. 2002). Thus, many bacteria produce multiple signal molecules (Fuqua et al. 2001; Withers et al. 2001; Camara et al. 2002) that are components of complex regulatory hierarchies responsible for controlling signal molecule production, detection, and response (Atkinson et al. 1999; Winzer and Williams 2001). At the molecular level, quorum sensing requires a synthase plus a signal transduction system for producing and responding to the signal molecule. The latter usually involves either a response regulator or sensor kinase protein or both (see Two-component signal transduction systems) (Swift et al. 2001; Williams 2002). While there is, as yet, no clear-cut evidence for a molecularly conserved quorum-sensing system throughout the bacterial kingdom, the *luxS* gene and a furanone-related molecule termed AI-2 (for autoinducer-2) have been suggested to fulfill such a role (Bassler 2002). However, many bacteria (e.g. *P. aeruginosa*) do not possess *luxS* and hence do not produce AI-2 (Winzer et al. 2002a). Furthermore, since LuxS is a key metabolic enzyme in the activated methyl cycle responsible for recycling *S*-adenosylmethionine (SAM) (Winzer et al. 2002a, b), phenotypes associated with mutation of *luxS* are often not a consequence of a defect in cell-to-cell communication but the result of the failure to recycle SAM metabolites (Winzer et al. 2002a, 2004).

The most intensively studied quorum-sensing systems in gram-negative bacteria utilize *N*-acylhomoserine lactone (AHL) quorum-sensing signal molecules (Swift et al. 2001; Whitehead et al. 2001; Fuqua and Greenberg 2002). AHLs consist of a homoserine lactone ring attached, via an amide bond, to an acyl side chain. Naturally occurring AHLs containing an acyl side chain ranging from four to 18 carbons in length have been identified, and this chain may be saturated or unsaturated and bear either a hydroxy-substituent or an oxo-substituent, or no substituent on the carbon at the 3 position (see Figure 8a). AHLs are produced by a number of human pathogens, including *Aeromonas*, *Burkholderia*, *Brucella*, *Serratia, Pseudomonas*, and *Yersinia* species (Table 9), but not by *E. coli* or *Salmonella*.

The two central players of AHL-dependent quorum-sensing systems typically belong to the LuxI and LuxR protein families, which function as AHL synthases and transcriptional regulators, respectively (Withers et al. 2001). AHLs with a short acyl side chain passively diffuse out of the cell, whilst those with a long acyl side chain are pumped out. Once in the extracellular milieu, AHLs accumulate until a sufficient concentration is reached, enabling the binding to and activation of the transcriptional regulator LuxR to form a complex responsible for activating or repressing specific sets of target genes. The gene encoding the AHL synthase may itself be activated resulting in a positive autoinduction circuit through which the AHL signal molecule controls its own synthesis (Figure 8b). AHL synthases distinct from the LuxI family have also been identified, e.g. the LuxM family of *Vibrio* species (Milton et al. 2001), and alternative mechanisms for responding to AHLs have also been described (Miller et al. 2002).

MULTISIGNAL QUORUM SENSING IN *P. AERUGINOSA*

In the opportunistic human pathogen *P. aeruginosa*, a complex quorum-sensing hierarchy plays a central role in the regulation of virulence and contributes to the late stages of biofilm maturation (Sauer et al. 2002; Kjelleberg and Molin 2002). *P. aeruginosa* possess two AHL-dependent quorum-sensing systems, termed LasRI and RhlRI. LasI and RhlI are LuxI homologs that direct the synthesis of *N*-(3-oxododecanoyl) homoserine lactone (3-oxo-C12-HSL) and *N*-butanoylhomoserine lactone (C4-HSL), respectively (Pearson et al. 1994; Winson et al. 1995). 3-Oxo-C12-HSL and C4-HSL are responsible for activating the LuxR homologs LasR and RhlR, respectively. Together, *las* and *rhl* form a regulatory hierarchy in which the LasR/3-oxo-C12-HSL system regulates the *rhlRI* genes. Moreover, the target genes regulated via *las* and *rhl* overlap considerably (Whiteley et al. 1999), and recently a third LuxR homolog (QscR) has been identified that further modulates their expression (Chugani et al. 2001). The important contribution that quorum sensing makes to the pathogenicity of *P. aeruginosa* has been clearly demonstrated in animal, plant, and nematode experimental infection models. Furthermore, the isolation of AHLs from infected body fluids (e.g. sputa) and tissues has confirmed that AHLs are produced by *P. aeruginosa* in vivo during human infections (Camara et al. 2002). Interestingly, AHLs

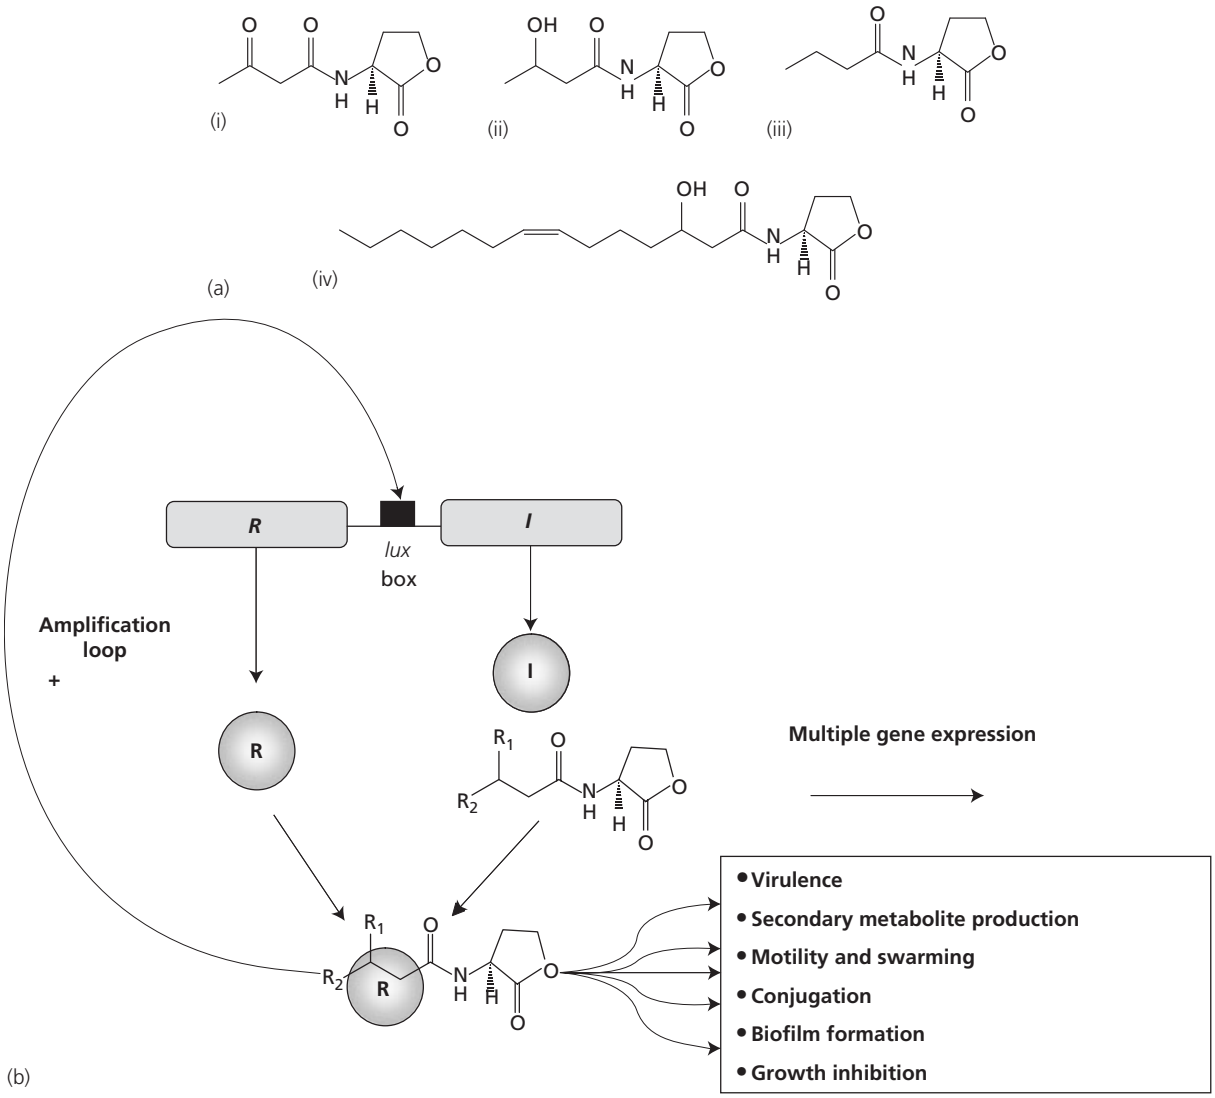

Figure 8 N-*Acylhomoserine lactone (AHL)-mediated quorum-sensing.* **(a)** *Example structures showing diversity of AHLs with either (i) -oxo (3-oxo-C_4HSL), (ii) -hydroxy (3-hydroxy-C_4HSL), or (iii) no substitutent (BHL) at the 3-carbon position of the acyl side chain. An AHL with an unsaturated acyl side chain (3-hydroxy-$C_{14:1}$HSL) is also shown (iv).* **(b)** *LuxRI/AHL-dependent signal circuitry. The 'R' and 'I' genes are homologs of the* Vibrio fisheri luxR *and* luxI *genes, which are arranged differently depending on bacterial species (they can be convergent, divergent, in tandem, or unlinked). The I protein directs the synthesis of AHLs, which exit the cell and are taken up into neighboring bacterial cells. Here, AHLs bind to and activate the response regulator (R) and this complex activates or represses the expression of multiple target genes by binding to conserved DNA sequences (*lux box*). In many cases the R protein/AHL complex also activates the* I *gene, creating an amplification loop resulting in a rapid increase in* I *gene expression and AHL production. Reproduced from Camara et al. (2002)*

such as 3-oxo-C12-HSL may also function as virulence determinants in their own right since they exhibit proinflammatory, immune modulatory, and vasorelaxant properties (Telford et al. 1998; Lawrence et al. 1999; Smith et al. 2001). Since T-cell responses constitute an important component of the host immune defense against *P. aeruginosa*, the 3-oxo-C12-HSL-mediated suppression of T-cell activity is likely to be advantageous to this pathogen.

Apart from AHLs, *P. aeruginosa* also produces a third quorum-sensing signal molecule, which is essential for the expression of many *rhl*-dependent phenotypes as well as biofilm development (Diggle et al. 2003). This is the pseudomonas quinolone signal (PQS) (2-heptyl-3-hydroxy-4-quinolone), which structurally resembles the 4-quinolone antibiotics and several antimalarial drugs (Pesci et al. 1999). PQS, like the AHLs, has been detected in the sputum of CF patients infected with *P. aeruginosa*, indicating that this signal molecule is also produced in vivo during infection. *P. aeruginosa* also produces a number of cyclic dipeptides (diketopiperazines) that are capable of cross-activating or antagonizing AHL-regulated processes, although their physiological function remains unclear (Holden et al. 1999).

Table 9 N-*Acylhomoserine lactone (AHL)-mediated gene regulation in different organisms*

Bacterium	LuxR/I	Major AHL	Phenotypes
Pseudomonas aeruginosa	LasR, LasI	3-Oxo-C12-HSL	Exoenzymes, Xcp secretion apparatus, biofilm maturation, RlhR
	RhlR, RhlI	C4-HSL	Exoenzymes, cyanide, RpoS, lectins, pyocyanin, rhamnolipd
Burkholderia cepacia	CepR, CepI	C8-HSL	Protease, siderophore
Chromobacterium violaceum	CviR, CviI	C6-HSL	Antibiotics, violacein pigment, exoenzymes, cyanide
Yersina pestis	YpeR, YpeI	Unknown	Unknown
Yersina enterocolitica	YenR, YenI	C6-HSL, 3-Oxo-C6-HSL	Motility and swamming
Yersina pseudotuberculosis	YpsR, YpsI	3-Oxo-C6-HSL	Bacterial motility and clumping
	YtbR, YtbI	C8-HSL	Unknown
Aeromonas hydrophila	AhyR, AhyI	C4-HSL	Extracellular protease, biofilm formation
Brucella melitensis	Unknown	C12-HSL	Inhibition of *virR/virS*

The potential contribution of quorum-sensing to the development and maturation of *P. aeruginosa* biofilms has been the subject of much debate and controversy. *P. aeruginosa lasI* mutants, for example, were reported to be unable to form a highly structured biofilm community (Davies et al. 1998), which could be more readily dispersed by detergents than wild-type biofilms. The in vivo relevance of this finding has also been indicated by evaluation of quorum-sensing-dependent biofilm development in the murine model of corneal infection (Zhu et al. 2002). However, it is unlikely that quorum-sensing is the only important effector, since biofilm-associated communities will exploit all available adaptive mechanisms and the corresponding network of regulatory activities (Kjelleberg and Molin 2002). Indeed, mathematical models (Wimpenny and Colasanti 1997; Van Loosdrecht et al. 1997) have illustrated that biofilm formation is a predictable consequence of the physicochemical conditions in the biofilm environment, indicating that the bacterial cells do not perceive that they are within a biofilm but simply respond to local environmental conditions (such as stress and nutrient gradients). Nevertheless, it is clear that many genes important for biofilm development and maturation are subject to AHL-dependent quorum-sensing control in *P. aeruginosa* and in other gram-negative bacteria.

THE STAPHYLOCOCCAL *AGR* SYSTEM

In gram-positive bacteria, quorum-sensing signal molecules are generally small, modified peptides, and the transduction of such signals usually involves a TCST phosphorylation cascade that ultimately triggers target gene expression (see Two-component signal transduction systems). The opportunistic human pathogens *S. aureus*, *Enterococcus faecalis*, and *Str. pneumoniae*, as well as *Bacillus subtilis*, regulate many cellular processes in this way (Novick and Muir 1999; Dunny and Leonard 1997).

The staphylococci, for example, produce quorum-sensing signal molecules termed autoinducing peptides (AIP). These are cyclic peptide thiolactones containing between seven and nine amino acid residues. In *S. aureus* and *Str. epidermidis*, these are produced via the *agr* regulatory locus, which also controls the production of multiple cell-wall colonization factors and exotoxins (Winzer and Williams 2001; Novick and Muir 1999; Otto 2001). The gene *agr* consists of two divergent transcription units, RNAII and RNAIII, controlled via the P2 and P3 promoters, respectively (Figure 9). While RNAIII is the Agr effector molecule, the P2 operon consists of four genes, *agrABCD*. AgrA and AgrC constitute a response regulator and sensor kinase, respectively, while the AIP is derived from an internal fragment of the AgrD protein. The transmembrane protein AgrB is responsible for processing AgrD and secreting the AIP signal molecule.

AIPs interact with the membrane-bound sensor kinase AgrC to activate the response regulator AgrA, located in the cytoplasm. Activation of *agr* occurs through the initiation of a phosphorylation cascade, resulting in the production of more AIP (via the P2 operon) and the effector RNA molecule, RNAIII via P3. At high *S. aureus* cell densities, *agr* represses the expression of genes coding for cell-surface proteins involved in colonization, while activating the expression of genes coding for exotoxins and tissue-degrading exoenzymes, Several experimental models of infection have highlighted a key role for the *agr* locus in the virulence of *S. aureus* (Novick and Muir 1999).

S. aureus strains can be subdivided into four AIP groups (I–IV), in which the AgrD-derived AIP of one group can cross-activate the *agr* response (and thus virulence) in other strains of that group but inhibit the *agr* response of members of other groups (Ji et al. 1997). While the primary amino acid sequence is different for each AIP, they all share a common central cysteine that is located five amino acid residues from the C-terminal amino acid. The AIPs are not linear peptides but contain an intramolecular thiol ester linkage between the sulfydryl group of the

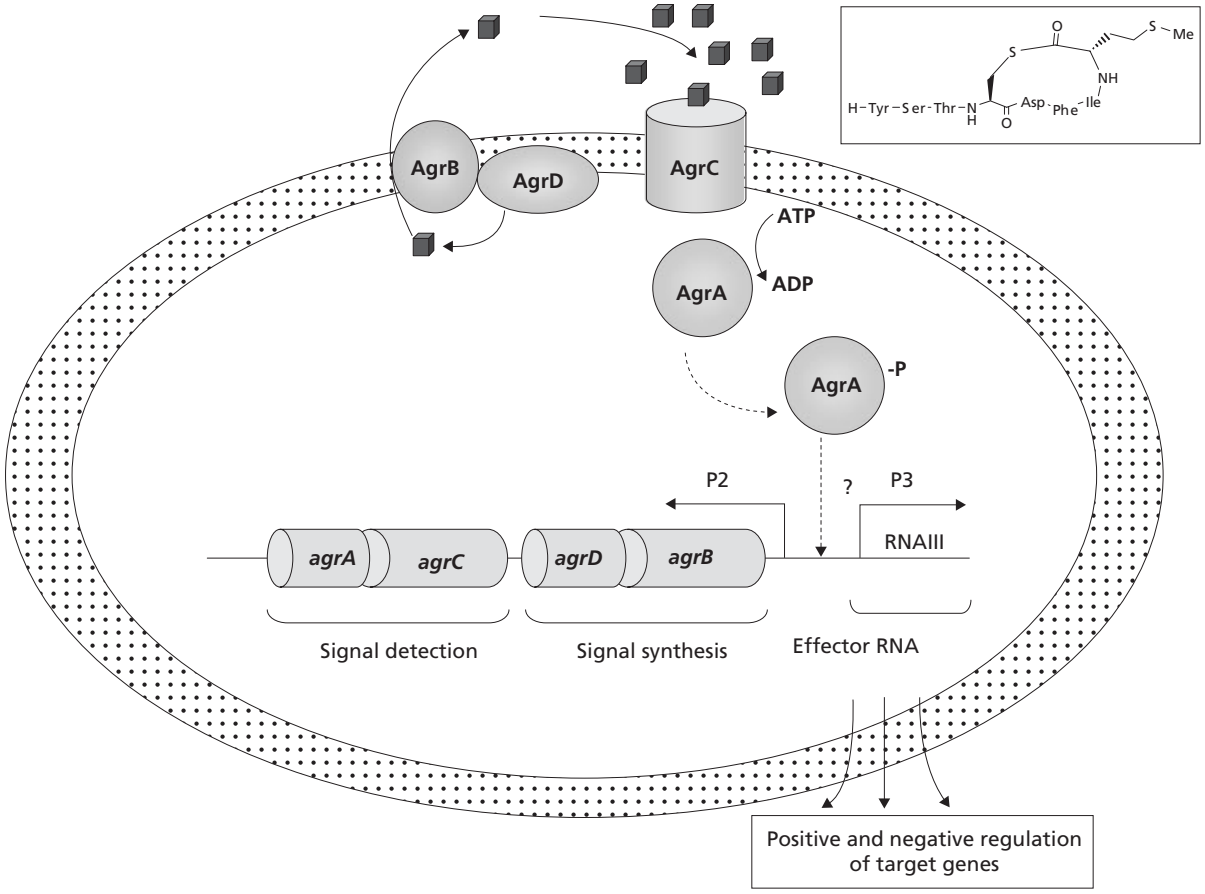

Figure 9 Agr-*mediated quorum-sensing circuitry. The* agr *locus consists of two divergent transcriptional units. One is expressed from the P2 promoter and consists of* agrABCD, *which encodes for the proteins responsible for generating and sensing the peptide signal molecule.* AgrB *acts on the peptide derived from* agrD *to yield the signaling peptide and also to effect its export out of the cell. Once a critical extracellular concentration of the peptide is reached, it interacts with the AgrC membrane-associated sensor protein, causing it to autophosphorylate. This phophate is then transferred to the response regulator, AgrA, which then activates the expression of RNAIII from the P3 promoter. The effector molecule, RNAIII, mediates the changes in expression of multiple target genes, resulting in the* agr *response. An autoinduction feedback loop results in more peptide signal, since* agrBD *are amongst the activated genes. The insert in the top right-hand corner shows the structure of the quorum-sensing peptides produced by group I* Staphylococcus aureus. *Redrawn from Camara et al. (2002).*

conserved cysteine and the α-carboxyl group of the C-terminal amino acid. This thiolactone structure is essential for full biological activity and, consistent with the concept of cell population density sensing, a critical threshold concentration (in the nanomolar range) of the AIP is required to trigger an *agr*-dependent response (Ji et al. 1997; McDowell et al. 2001). AIP antagonists therefore offer a novel means of controlling staphylococcal infections, since they inhibit exotoxin (e.g. toxin shock syndrome toxin, TSST-1) and exoenzyme (e.g. lipase) production. In a mouse subcutaneous abscess infection model, coinoculation of a virulent group I strain with the group II AIP resulted in reduction in the virulence of the group I strain (Mayville et al. 1999). Other staphylococcal species such as *S. epidermidis* and *S. lugdunensis* also produce AIPs that are cross-inhibitory with those of *S. aureus*. Thus, it seems that staphylococci have evolved an innate mechanism for coupling their pathogenic potential with a means to ward off potential competitors.

EVOLUTION OF PATHOGENS WITHIN THEIR HOST

Although pathogens are capable of integrating the diverse environmental signals encountered during the progress of infection to control virulence factor deployment, other strategies are also employed. For example, the capsules of *N. meningitidis* undergo phase variation such that they are expressed at late stages of infection to provide protection against the immune system, and not when their presence would hinder intimate adhesion to host cells, which is required for invasion during the early stages (Deghmane et al. 2002). Phase variation in *N. meningitidis* can occur by several different mechanisms: capsule biosynthesis genes can be acquired or lost allowing antigenic variation, plus their expression can be

regulated by slip-strand mispairing. This mechanism regulates a range of virulence factors of *N. meningitidis* and other bacteria such as *H. influenzae*, and relies upon the presence of an extended nucleotide repeat, which can loop out, resulting in a deletion that results in disruption of the reading frame and loss in gene expression (Moxon et al. 1994). The existence of such mechanisms suggests that the host exerts a certain selective pressure upon the pathogens it harbors. This is perhaps well illustrated by the apparent continuous microevolution of *H. pylori* within its cognate host (Israel et al. 2001). The highly diverse organism *H. pylori* persists in the human stomach and induces chronic gastritis, which may progress to peptic ulceration, noncardia gastric adenocarcinoma, or gastric lymphoma during the life of the host. The differential development of these clinical sequelae probably depends on differentially represented bacterial determinants, host characteristics, and interactions between the host and the bacterium throughout their time of coexistence.

Although *H. pylori* appear to exhibit a clonal population structure over short periods of time, isolates obtained from different individuals exhibit substantial genetic diversity, consistent with extensive recombination and a panmictic (a population derived from a single organism) population structure (Suerbaum et al. 1998). Strains may differ in their possession of point mutations in highly conserved genes (Achtman et al. 1999), the presence of nonconserved and/or mosaic forms of genes (Akopyants et al. 1998; Censini et al. 1996; Peek et al. 1998; Pride et al. 2001), and chromosomal organization (Taylor et al. 1992; Jiang et al. 1996; Alm et al. 1999). These variations may be acquired through horizontal genetic exchange or spontaneous mutation (Suerbaum et al. 1998; Achtman et al. 1999). Comparison of isolates of the sequenced *H. pylori* strain J99, after a 6-year interval from its human source patient, revealed genetic divergence amongst the isolates and between them and the original stain (Israel et al. 2001). Thus, it appears that within an apparently homogeneous population as determined by macroscale comparison (randomly amplified polymorphic DNA, polymerase chain reaction (PCR), and DNA sequencing of four unlinked genetic loci), genetic differences emerged among single-colony isolates of *H. pylori*. The acquisition of genes originating from distinct strains suggests that there may have been an additional subpopulation of *H. pylori* strain J99 possessing these open reading frames (ORF), or that another strain of *H. pylori* or closely related organism was transiently present in the stomach. The implied continuous state of genetic flux may allow *H. pylori* to adapt rapidly to changing conditions in its current host throughout the extended period of coexistence, as well as priming it for colonization of a new host. *H. pylori* strain variation may hinge upon gene mosaicism (see below) or the presence of segments of nonconserved DNA. This is perhaps best illustrated by the gene encoding the vacuolating cytotoxin (VacA) and the cytotoxin associated antigen (CagA), which is encoded on a pathogenicity island (PAI).

VacA is a member of the family of autotransporter proteins (Cover 1996; Telford et al. 1994) (see Table 10 for other members), and as such is produced as a precursor polypeptide in the cytoplasm. An N-terminal targeting domain delivers the autotransporter to the inner membrane and is cleaved during translocation to

Table 10 *Examples of members of the autotransporter family, amended from Henderson and Nataro (2001)*

Bacterium	Autotransporter
Neisseria meningitidis	IgA protease
Neisseria gonorrhoeae	IgA protease
Haemophilus influenzae	IgA protease, adhesin (Hap, Hia, Hsf)
Helicobacter pylori	VacA cytotoxin, BabA adhesin
Shigella flexneri	IcsA
Bordetella spp.	Adhesins (Pertactin, TcfA, Vag8), serum resistant factor (BrkA)
Dichelobacter nodusus	Putative elastases (BprV, BprB, AprV2, BprX)
Moracella catarrhalis	Adhesin (UspA1, UspA2h), serum resistance protein (UspA2)
Pasteurella haemolytica	Ssa1 protease
Pseudomonas aeruginosa	EstA esterase
Pseudomonas fluorescens	Proteases (PspA, PspB)
Ricettsiales	Adhesin (rOmpA, rOMPB)
Salmonella typhiumurium	Esterase ApeE
Serratia marcesens	Proteases (PrtS, PrtT, Ssp-H1, Ssp-H2)
Shigella flexneri	Proteolytic (SepA, SigA), mucinase (Pic), mediator of intracellular motility (IcsA)
Xenorhabdus luminescens	Lipase (PlaA)
Pathogenic *Escherichia coli*	AIDA-I adhesins (AIDA-I, TibA), proteolytic toxin (EspP, Pet, Sat), hemagglutinin (Tsh), mucinase (Pic), biofilm formation (Ag43), EspC.

the periplasm. This translocation may be achieved via the SRP/Sec pathway (Henderson et al. 1998; Sijbrandi et al. 2003). The C-terminal domain is proposed to insert into the outer membrane forming a β-barrel through which the mature protein (or passenger domain) is translocated to the extracellular medium. Cleavage of this C-terminal domain, which may be mediated by the passenger protein or surface proteases (Henderson et al. 1998; Henderson et al. 2000), then releases the mature protein (Figure 4). VacA shows homology to this family both by possession of an extended N-terminal signal peptide and by the presence of a C-terminal domain, which shows homology to other autotransporters and is cleaved during secretion (Cover 1996; Schmitt and Haas 1994). Once secreted, the approximately 90-kDa passenger domain of VacA is processed further, yielding subunits of approximately 58 and 37 kDa. These monomers combine to form dodecamers or tetradecamers (Cover et al. 1997) with a flower-like rosette structure (Lupetti et al. 1996). In acidic conditions, these oligomers dissociate back into monomers, exposing hydrophobic regions and allowing efficient insertion into target membranes (Molinari et al. 1998b).

Once released from the bacterial cell, VacA damages eukaryotic cells, causing mitochondrial damage (Kimura et al. 1999; Galmiche et al. 2000), inducing apoptosis (Galmiche et al. 2000; Kuck et al. 2001), increasing permeability of polarized monolayers (Papini et al. 1998; Pelicic et al. 1999), disrupting antigen presentation (Molinari et al. 1998a), and interfering with vacuolar transport in the late endosomal pathway, resulting in the formation of characteristic vacuoles (Cover and Blaser 1992; Molinari et al. 1997). Although all *H. pylori* strains analyzed to date contain *vacA*, its sequence varies, a phenomenon known as mosaicism. The nucleotide sequence encoding the N-terminal signal region may be one of four variants (s1a, s1b, s1c, or s2), whilst the mature passenger domain may contain a segment of an m1, m2a, or m2b (Atherton et al. 1995; van Doorn et al. 1998) subtype. The s1 and m1 types have been associated with increased virulence of *H. pylori*, since strains bearing this combination are most frequently associated with more serious disease states in humans (Atherton et al. 1995). The more pathogenic strains of *H. pylori* (type I strains) also possess the *cag* PAI, an element lacking in strains associated with milder clinical outcomes (type II strains).

The *cag* PAI encodes a type IV secretion system (TFSS) (see Protein secretion and Figure 4) that facilitates the injection of bacterial proteins directly into eukaryotic cells. Following attachment to the surface of eukaryotic cells, CagA is delivered into the host cell by proteins encoded by other genes on the *cag* PAI (Asahi et al. 2000; Backert et al. 2000; Odenbreit et al. 2000; Segal et al. 1999; Stein et al. 2000). Intracellular CagA is tyrosine phosphorylated by a host cell kinase of the Src family (Selbach et al. 2002; Stein et al. 2002), whereupon it interacts with the SHP-2 phosphatase initiating signaling events that lead to dramatic cellular elongation (the 'humming-bird' phenotype) (Higashi et al. 2002). The precise molecular events occurring throughout this alteration of the actin cytoskeleton remain unclear, although the involvement of small GTPases is possible (Covacci and Rappuoli 2003).

Independent of *cagA*, the *cag* PAI initiates the activation of NF-κB and the expression of proinflammatory cytokines, such as IL-8 (Crabtree 1998). The latter requires that the *cag* PAI encodes a functional TFSS.

HOST RESISTANCE TO INFECTION

Many of the bacterial virulence determinants described above contribute to pathogen evasion of host defenses. Resistance/immunity in higher animals can be divided into innate and acquired (adaptive) immunity. In an evolutionary context, innate immunity is considered to be the most ancient form of defense against invading microorganisms. It is present from birth, functions nonspecifically against diverse microorganisms, and, in contrast to acquired immunity, does not become more efficient on subsequent exposure to the same organisms or antigens. Acquired immunity, on the other hand, is based on the generation of an antibody response towards specific antigens associated with infecting pathogens. It is extremely flexible and is able to mount a response to virtually any antigen presented. A unique feature of the acquired immune response is the memory of previous encounters with an antigen and the capacity to mount an improved response during subsequent exposures.

Innate immunity

Innate immunity refers to the nonspecific defense mechanisms that a host uses immediately or within several hours following exposure to an antigen. There are numerous factors that contribute to the innate immunity of a higher organism and these can be subdivided into: (1) anatomical barriers; (2) mechanical removal; (3) nutritional restriction; (4) bacterial antagonism; and (5) common pattern recognition.

ANATOMICAL BARRIERS

Anatomical barriers are tough intact layers that prevent the entry and colonization by microorganisms. Examples include the skin and the mucous membranes.

The skin, consisting of the epidermis and the dermis, is dry and acidic and has a temperature less than 37°C. These conditions are not favorable for bacterial growth. The dead keratinized cells that make up the surface of the skin are continously being sloughed off, so that microbes that do colonize these cells are constantly

being removed. The hair follicles and sweat glands, which provide potential entry sites, produce lysozyme and toxic lipids that can kill bacteria. Also, beneath the surface, is the skin-associated lymphoid tissue (SALT), which contains cells that kill incoming microorganisms and initiate acquired immune responses by sampling antigens on the skin.

Mucous membranes line body cavities that are open to the exterior environment, such as the respiratory tract, the gastrointestinal tract, and the genitourinary tract. Mucous membranes are probably the most important site of entry of pathogenic bacteria into the host body. Mucosal surfaces are composed of an epithelial layer that secretes mucus, which acts as a physical barrier, trapping microorganisms and preventing deeper penetration into the tissues. Mucus contains the bactericidal protein lysozyme, which degrades bacterial peptidoglycan (leading to the lysis of bacterial cells), as well as secretory IgA, which prevents bacteria from attaching to the epithelial layer of cells. In addition, secretions from mucus membranes contain the iron-transporting protein lactoferrin, which plays a major role in mucosal defence. Lactoferrin not only withholds iron from infecting bacteria (see Motility), but also is capable of disrupting bacterial biofilms (Singh et al. 2002) and degrading bacterial virulence factors (such as the Hap adhesins and IgA proteases of *H. influenzae*) via its serine protease activity (Hendrixson et al. 2003). Lactoferrin also possesses immunoregulatory functions and bactericidal activity and can neutralize the toxic effects of LPS (Caccavo et al. 2002). Mucus also contains lactoperoxidase, which generates toxic superoxide radicals that rapidly kill bacteria. It has also been suggested that the resident normal microbial flora of the mucosa exclude colonization by potentially harmful bacteria. Beneath the mucosal surface is mucosa-associated lymphoid tissue (MALT), which contains cells that destroy invading bacteria and subsequently initiate an acquired immune response.

MECHANICAL REMOVAL OR THE PHYSICAL FLUSHING OF MICROORGANISMS FROM THE BODY

Cilia on the surface of the epithelial cells that line mucous membranes, such as those in the respiratory tract, propel mucus and trapped bacteria upwards towards the throat, where it is swallowed. The acid pH of the stomach breaks mucus down and kills any bacteria present. Coughing and sneezing, in a similar way, removes bacteria from the respiratory tract that have become trapped in the mucus. Although vomiting and diarrhea are considered characteristic symptoms of particular diseases, they also can be considered part of the host defense, since they effectively remove pathogens and toxins from the gastrointestinal tract. It should be noted that the flow of fluids, such as urine, tears, saliva, perspiration, and blood from injured blood vessels, is also important for the mechanical removal of pathogens from the host body.

NUTRITIONAL RESTRICTION

Nutrient-depriving host defense molecules include transcobalamins (which bind vitamin B12), calprotectin (which binds zinc), and lactoferrin (which sequesters iron). Iron is one essential nutrient for both host and pathogen (see Iron scavenging). During the course of infection, the human body makes considerable efforts to make iron unavailable to microorganisms for growth; this is called the hypoferremic response. Much of this is due to production of IL-1α (also known as leukocyte-endogenous mediator (LEM)) which acts to lower free iron in tissues and body fluids. However, there are other factors that contribute to the lowering of available free iron during infection, including: (1) decreased intestinal dietary iron uptake; (2) a reduction in plasma iron levels and increased synthesis of the iron storage protein ferritin; (3) increased synthesis of lactoferrin and transferrin; and (4) release of lactoferrin at sites of microbial infection, such as the mucous membranes.

BACTERIAL ANTAGONISM

Approximately 100 trillion bacteria and other microorganisms reside in or on the human body as the normal body flora. These are considered to exclude potentially harmful opportunistic pathogens by the production of, for example, fatty acids and antibacterial peptides, such as bacteriocins. The normal flora may also influence the growth of invading pathogens by depletion of, and competition for, the available nutrients. An example of the prevention of disease by bacterial antagonism is that of the severe antibiotic-associated colitis caused by *Clostridium difficile*. This anerobe, which cannot grow within a normal gut flora, will infect and colonize when the gut flora microecology is altered by, for example, antibiotics.

COMMON PATTERN RECOGNITION

Common pattern recognition has evolved to identify a few highly conserved molecules present in or on many different microorganisms. The structures recognized are termed pathogen-associated molecular patterns and include LPS, peptidoglycan, LTA, the sugar mannose (which is common in microbial polysaccharides but rare in those derived from higher organisms), bacterial DNA, double-stranded RNA (from viruses), and glucans (from fungal cell walls). Most body defense cells have pattern-recognition receptors (Toll-like receptors (TLR)) for these common pathogen-associated molecular patterns and so, upon infection, there is an immediate response to invading microorganisms. Pathogen-associated molecular patterns can also be recognized by the blood-borne proteins that initiate complement.

The lipid A component of LPS/LOS was the first agonist shown to bind and activate TLRs. These

constitute a family of distinct proteins characterized by an intracellular domain with homology to that of the IL-1 receptor and containing extracellular leucine-rich repeats. TLRs activate the immune system to recognize conserved macromolecular components of pathogens and, through this interaction, activate the immune system. Pathogen recognition leads to the initiation of defensive protective actions, which include the production of reactive oxygen intermediates and the secretion of inflammatory cytokines, such as IL-1, interleukin-12 (IL-12), interferon-γ (IFN-γ), and TNF-α (Raetz and Whitfield 2002). These cytokines activate natural killer cells and also initiate a cascade of signals to cells of the adaptive arm of the immune response, preparing them for the development of antigen-specific immune responses. Activation of TLRs by lipid A also results in the production of defensins, which consist of several distinct families of antibacterial, antifungal, and antiviral peptides (Heine and Lien 2003).

TLRs direct these effects by activating host signal transduction processes, including the transcription factor NF-κB and the MAP kinases, p38, and c-jun. Differences between signals generated by alternative TLRs are emerging. Each TLR is activated by a different microbial surface component, e.g. TLR4 is activated primarily by bacterial LPS and LTA. Both LPS and LTA first bind to the CD14 receptor and are subsequently transferred to the TLR4 complex. LTA can bind directly to CD14, but LPS must be delivered to CD14 by LPS-binding protein (LBP). TLR4 signals through an accessory protein termed MyD88 to activate the transcription factors, NF-κB, Elk-1, and AP-1. TLR6 is also activated by LPS and shares the same signaling pathway as TLR4, as does TLR2 (activated by bacterial lipoarabinomannan (LAM) and peptidoglycans (PGN)). When activated by bacterial lipoprotein (BLP), TLR2 mediates both apoptosis and NF-κB activation. If NF-κB is inhibited downstream of MyD88, then apoptosis occurs through the activation of caspase 8 (Aliprantis et al. 2000). TLR2 is also responsible for the recognition of the yeast cell-wall particle zymosan. It is believed that zymosan acts through the CD14 receptor to influence TLR2, shown by high levels of downstream NF-κB in $CD14^+/TLR2^+$ macrophage exposed to zymosan, as compared with NF-κB levels observed in $CD14^-/TLR2^+$ macrophage exposed to zymosan. TLR2 is internalized after activation by zymosan; the yeast cell is also internalized with TLR2. TLR2 signals the production of TNFα, through NF-κB pathway, from the phagocytosed vesicle (Underhill et al. 1999).

TLR9 is responsible for the recognition of extracellular CpG islands of bacterial DNA. Two mechanisms for TLR9 activation are considered to exist. TLR9 bound to extracellular CpG fragments may be endocytosed, or alternatively phagosome located TLR may interact with phagosome internalized bacteria. The result of either of these is the activation of the NF-κB pathway from the endocytosed vesicle (Hemmi et al. 2000). TLR5 recognizes bacterial flagella and activates NF-κB pathway. The functions of TLR1, 3, 7, 8 and the recently cloned TLR10 (Chuang and Ulevitch 2001) are not yet known.

Acquired immunity

The lymphocyte-generated antibodies comprising the acquired immune system act in different ways. Some antibodies, such as IgG and IgE, function as opsonins, promoting phagocytic engulfment of bacteria. Antibodies, such as IgG, IgA, and IgM, bind to bacterial adhesins, pili, and capsules and block attachment to host cells. IgG and IgM can also activate the classical complement pathway, whilst IgA and IgM crosslink bacterial cells, enabling more efficient phagocytic clearance.

Bacteria evade antibody-mediated clearance in a number of ways (see Avoidance of host immune defenses), including antigenic variation of surface macromolecules, by the synthesis of surface components that mimic host tissue antigens, and by bacterial surface coating with host proteins, such as fibronectin and fibrinogen. By producing immunoglobulin-binding cell-wall proteins that bind the Fc portion of antibodies, bacteria such as *S. aureus* and *Str. pyogenes* can evade opsonization. Some bacteria produce immunoglobulin-degrading proteases, e.g. the IgA proteases of *H. influenzae*, *Str. pneumoniae*, *N. meningitidis*, and *N. gonorrhoeae*.

GENOMICS AND BACTERIAL PATHOGENICITY

Advances in molecular biology and, in particular, the ability to clone, express, and mutate specific genes have proved invaluable for defining the repertoire of virulence determinants employed by a pathogen. This in turn has resulted in the definition of Koch's molecular postulates (Falkow 1988; Joyce et al. 2002; Relman and Falkow 2001) for determining the relationship between a given virulence determinant and disease. The development of specific genetic strategies for identifying structural and regulatory genes that are essential for bacterial life in vivo, but not in vitro (in vivo expression technology (IVET) and signature-tagged mutagenesis (STM)) has provided many novel insights into the lifestyle of diverse pathogens. The information obtained from such experimentation can now be greatly enhanced by the availability of pathogen genome sequence information and the potential offered by DNA microarrays and proteomics for defining the global response of the pathogen to the host environment, and vice versa.

Several approaches can be used to analyze whole-genome sequences for candidate virulence factors, potential vaccine antigens, and novel antimicrobial

targets. By comparing predicted coding sequences with sequences in databases such as GenBank through use of the BLAST program (www.ncbi.nlm.nih.gov:80/BLAST) identifies matches to known genes involved in virulence. Approximately 20 percent of the predicted ORFs in a genome do not match anything in GenBank, while another 10–20 percent match genes of unknown function. Therefore, the comparative approach has been useful for recognizing good candidates for virulence genes among genes whose functions have been previously defined. While this in silico approach has not proved particularly useful for the discovery of novel virulence genes, the availability of such information on easily accessible electronic databases has made it a routine tool for studies of pathogenic microbes and prompted the development of experimental techniques, such as IVET and STM.

STM is a powerful tool for the identification of genes that are required for virulence and in vivo survival. It is a method for identifying mutants that are unable to replicate in vivo and therefore display an attenuated phenotype. A transposon is used for random mutagenesis of the bacterial genome. Each transposon has been prepared to carry a unique index region or signature tag. The unique tag can be amplified by PCR using standard regions flanking the tag and the resulting products used as a hybridization probe to identify the unique transposon that encodes it. The initial set of random insertion mutants are arrayed as a master, pooled, and then grown under either in vitro or in vivo conditions in an experimental animal model of infection. All the mutants that emerge from the in vitro and in vivo growth regimens are collected, their index regions amplified by PCR, and used to hybridize against the master array of original mutants. Mutants in the master array that do not hybridize with the tag sequences amplified from bacteria recovered from in vivo grown bacteria represent mutants that are attenuated and are unable to survive in vivo. Regions flanking the transposon insertions in mutants of interest are sequenced and compared with the genomic sequence databases to identify the inactivated gene(s). This powerful technique has been used to identify novel genes involved in pathogenesis for numerous pathogens, including *Salmonella*, *Neisseria*, and *E. coli* (Tang et al. 2001).

IVET is a method based on trapping promoters. Random genomic fragments are ligated in front of a promoterless reporter gene, the activity of which is used as an indication of transcriptional activity of the fused gene. Reporter genes that have been used include those that can allow auoxotrophy complementation IVET selection (e.g. *purA*), antibiotic IVET selection (e.g. *cat*), and recombinase-based IVET (RIVET), with which screening is achieved using a promoterless *tnpR* allele, as this cleaves a tetracycline resistance gene from elsewhere in the bacterial genome when produced. The suicide plasmids recombine into the chromosome by insertion–duplication, and fusion strains are passaged through an appropriate animal model before being collected from infected tissues and/or fluids. This strategy has been successfully used for *S. entirica* serovar Typhimurium, *Yersinia entercolitica*, *Streptococcus gorndonii*, *V. cholerae*, and *S. aureus* (Merrell and Camilli 2000).

CONCLUSIONS

Pathogenic bacteria exhibit coordinated responses to stimuli received from the external environment and during life on or within the host. These stimuli in turn impose differential selective pressures, which direct pathogen evolution. Certain bacteria have evolved strategies for avoiding the host immune system by invading host cells, while others have adopted measures for immune evasion while remaining adherent to host cell surfaces. Many pathogens produce tissue-damaging exotoxins and exoenzymes, which aid bacterial survival by increasing the availability of nutrients for growth, while simultaneously destroying tissue and host defenses. The coordinated deployment of these multiple virulence determinants is subject to tight regulatory controls through a variety of sensory pathways, some of which involve bacterial cell-to-cell communication. The ongoing unveiling of genomic, proteomic, and metabolomic information is likely to improve substantially our understanding of pathogen adaptive behavior and the host response, which in turn should provide new opportunities for the development of novel anti-infective measures.

Introduction	1	Monitoring for airborne bacteria	5
Bioaerosols	1	Summary	7
Airborne bacteria associated with adverse human health effects	4	References	7

INTRODUCTION

Bacteria are ubiquitous in the environment, capable of growing on virtually any surface and in most liquids when nutritional and environmental factors are favorable. Their presence in the air is the result of dispersal from a site of colonization and growth. This chapter will review the study of bacteria in the air that impact human health and the environment.

BIOAEROSOLS

A bioaerosol is a collection of airborne biological material consisting of cells, cellular fragments, and by-products of metabolism. This material can be present as particulate, liquid, and volatile organic compounds, and it may have biological activity on other organisms (Cox and Wathes 1995). Bacterial aerosols are generated in a variety of indoor environments and facilities and as a result of a variety of activities (Table 1), including dispersal from heating, ventilation, and air-conditioning (HVAC) systems, water-spray devices (e.g. showerheads, humidifiers), and flooring (Lighthart and Stetzenbach 1994). Bacterial aerosols are also generated by medical (Demers 2001; Nottrebart 1980) and dental (Depaola et al. 2002; Leggat and Kedjarune 2001) procedures, and patient (Shiomori et al. 2001, 2002) and animal care (Kaliste et al. 2002; Kowalski et al. 2002) practices, prompting cautionary measures to protect patients and staff from dispersed airborne bacteria. Talking and coughing generate bioaerosols from building occupants with droplet concentrations of 10^4–10^5 droplets/m^3 of air (Papineni and Rosenthal 1997). Manufacturing practices and biofermentation procedures can also generate bacterial aerosols (Abrams et al. 2000). Outdoors, bacterial aerosols are generated as a result of spray irrigation, wastewater treatment activity, wave splash, cooling towers, air-handling water-spray systems, and agricultural processes (Brandi et al. 2000; Burkhart et al. 1993; Hameed and Khodr 2001; Lighthart and Stetzenbach 1994; Lighthart and Mohr 1997; Pillai and Ricke 2002).

The particulate in a bioaerosol is generally 0.3–100 μm in diameter (Cox and Wathes 1995). Single bacterial cells range in size from 0.5 to 2.0 μm and are commonly spheres (cocci), rods (bacilli), or spirals. However, airborne bacterial cells are often present as aggregate formations of larger particles (Lighthart 1994). Aggregates of cells have different aerodynamic properties compared with single cells and they afford protection of individual cells from environmental stresses such as dessication, ultraviolet irradiation, and exposure to ozone in the atmosphere. Cell aggregates surrounded by a thin layer of water are commonly the result of dispersal from water sources by splash, rainfall, or mechanical disturbance (e.g. cooling towers, fountains). This often aids in the survivability of the cells while airborne. Airborne bacterial cells may also be associated with skin cells, dust, and other organic or inorganic material in a relationship that is commonly referred to as 'rafting.' Rafting cells are often found in bioaerosols generated from agricultural settings (e.g. during harvesting, tilling) and indoor environments. This formation affects the aerodynamic characteristics and the

dl = less than detection limit; NQ = not quantitated.

survival of the cells in the bioaerosol (Lighthart and Stetzenbach 1994).

Airborne particulate will remain airborne until settling on to surfaces occurs. Bioaerosols ranging in size from 1.0 to 5.0 μm generally follow the air stream while larger particles are more readily deposited on surfaces (Mohr 2002). The settling of the particles is affected by physical and environmental factors. Air currents, relative humidity, and temperature are the most important environmental parameters while the size, density, and shape of the cell or bacteria-containing particle are the most significant physical parameters (Mohr 2002; Pedgley 1991). These parameters also affect the survivability of the cells and their ability to colonize surfaces or liquid when deposited.

Relative humidity is the most important factor in the survival of bacterial cells with low humidity resulting in desiccation. The bacterial cell membrane is adversely affected by loss of water, resulting in loss of viability (Cox 1987; Israeli et al. 1994), and low relative humidity has been shown to increase the resistance of some bacteria to ultraviolet irradiation (Ko et al. 2000; Mohr 2002). Increased temperatures also decrease the viability of airborne cells (Ko et al. 2000; Mohr 2002).

Vegetative bacterial cells are more susceptible to environmental stresses than bacterial endospores and vegetative gram-negative bacilli are more susceptible than gram-positive cocci. The greater resistance of vegetative gram-positive cocci is due in part to the presence of pigment and the composition of their cell wall. Carotenoid pigments and photoreactivation mechanisms in gram-positive cocci afford protection from sunlight (Henis 1987). The cell wall of gram-negative bacteria is actually an outer membrane composed of mucopeptides linked to lipopolysaccharide with a thin outermost layer of peptidoglycan that is only 5–10 percent of the structure. When exposed to heat, the lipopolysaccharide may be released resulting in injury and/or death to the cell. Gram-positive cells have a peptidoglycan layer that comprises up to 80 percent of the cell wall, affording more protection from drying and heat stress (Marthi 1994). The integrity of the ribosomes in various bacterial genera also contributes to recovery of heat-injured cells (Henis 1987). Several models have been presented to explain the complex interactions of physical, environmental, and physiological factors of bacterial survival in aerosols (Mohr 2002).

Bacterial aerosols can elicit adverse human health effects, including infection, allergic reaction, inflammation, and respiratory disease. The primary route of exposure to aerosols is inhalation. Approximately 10 m^3 of air per day are inhaled by the average human (Lynch and Poole 1979), but some ingestion and dermal exposure may also occur. Large airborne particles are lodged in the upper respiratory tract (nose and nasopharynx) and particles <6 μm in diameter are transported to the lung. One- and two-micrometer-sized particles have the greatest retention in the alveoli of the lungs.

Mycobacterium tuberculosis and *Legionella pneumophila* are recognized as respiratory pathogens that are capable of causing severe disease, but aerosol transmission of other bacteria can also result in illness. Allergic reactions and irritant responses to the foreign proteins of bacterial cells and fragments, and reactions to by-products of bacterial metabolism can result in adverse health. Inflammatory responses (Liu et al. 2000) caused by bacterial fragments present in airborne dust and allergic reactivity to *Pseudomonas* in wood dust (Skorska et al. 2002) have been reported. Disease transmission between farm animals via aerosols is also documented (Brockmeier and Lager 2002).

AIRBORNE BACTERIA ASSOCIATED WITH ADVERSE HUMAN HEALTH EFFECTS

Mycobacterium species

The dispersal of airborne infectious *Mycobacterium tuberculosis* (Kaufmann and van Embden 1993), nontuberculosis mycobacteria (Contreras et al. 1988), and *M. leprae* (Bryceson and Pflatzgraft 1990) are associated with severe illness. The transmission of *M. tuberculosis* via bioaerosols from infected people occurs during coughing, talking, speaking, laughing, and sneezing (Rubin 1991), and exposure to infectious aerosols has been reported during air travel (Driver et al. 1994). Nosocomial *M. tuberculosis* infections have been reported resulting from aerosols generated by the operation of suctioning instruments during treatment, manipulation of tuberculosis ulcers, drainage of necrotic tissue, and exposure during autopsy (Nottrebart 1980). Installation of ultraviolet lights in areas of increased risk of exposure to *M. tuberculosis* and other infectious bioaerosols has been shown to be effective, but efficacy was affected by the number of lights and the air exchange rate and presence of air currents in the area being treated (Ko et al. 2002).

Laboratory experiments with *Mycobacterium terrae* isolated from a water damaged building demonstrated inflammatory responses in mouse lung (Jussila et al. 2002) and mycobacteria of the *M. avium* complex commonly isolated from soil, water, and the air are associated with respiratory infection in immunocompromised patients (Wolinsky 1979). Discharge of 10^8 *M. leprae* bacilli has been reported from the nose blow of an untreated person with leptomatous Hansen's disease (leprosy) (Stewart-Tull 1982).

Legionella

Legionella pneumophila is a vegetative gram-negative bacterium that is ubiquitous in freshwater environments worldwide (Fliermans et al. 1981; Steinert et al. 2002). Exposure to *L. pneumophila* via inhalation of the bacterium in contaminated aerosols and the replication of *L. pneumophila* in macrophages results in severe pneumonia termed legionnaires' disease. The first reporting of this disease followed the outbreak of respiratory illness among American Legion conventioneers in Philadelphia in 1976 (Fraser et al. 1977). Since that time an estimated 10 000–15 000 cases per year are reported in the USA (Marston et al., 1993). Nineteen other *Legionella* species are also human pathogens, often causing disease in immunosuppressed patients (Muder and Yu 2002). Pontiac fever is a mild flu-like syndrome attributed to the inhalation of *Legionella* that cannot replicate in host tissue (Fields 2002; Kaufman et al. 1981).

Fraser (1984) developed a framework for causation of a legionnaires' outbreak that detailed six factors that must occur. These factors are: (1) a reservoir of legionella must be present; (2) amplifying factors must occur to permit the concentration of legionella to increase; (3) the legionella must be dispersed resulting in human exposure; (4) the legionella must be virulent to humans;

(5) the legionella must be delivered to the appropriate site in the human host; and (6) the host must be susceptible to infection by the legionella. Although the organism is present in most freshwaters, it survives as an intercellular parasite of protozoa, thereby resulting in protection for the bacterium.

Exposure to *Legionella*-contaminated aerosols occurs as the result of mechanical air-conditioning systems with water-spray components, cooling towers, and aerosol-generating water devices (e.g. showerheads, faucets, whirlpool tubs, decorative fountains, humidifiers), but no human-to-human transmission has been documented (Mohr 2002).

Other gram-negative bacteria

Airborne gram-negative bacteria are associated with animal facilities with *Escherichia coli*, *Pantoea* (*Enterobacter*) *agglomerans*, *Pseudomonas* spp., and *Acinetobacter* spp. commonly isolated in cow barns, pig houses, and poultry barns (Zucker et al. 2000). Wastewater treatment plants (Brandi et al. 2000; Brenner et al. 1988; Crawford and Jones 1979; Kenline and Scarpino 1972) and recycling facilities (Reinthaler et al. 1999) also disperse gram-negative bacteria into the air. Dutkiewicz et al. (2001b) reported skin-test reactivity of herb-processing workers to extracts of *Alcaligenes faecalis*. These bacteria can cause a variety of health problems, especially to the young, elderly, and immunocompromised.

Endotoxin

Endotoxins are biologically active materials that affect humoral and cellular host mediation systems (Bradley 1979) and affect many organ systems (Hewett and Roth 1993). Endotoxin is an integral component of the gram-negative bacterial cell wall that is released during active cellular growth and after cell lysis (Bradley 1979). It has also been reported that endotoxin is shed in membrane vesicles when the organisms are associated with organic dust (Dutkiewicz et al. 1992).

Exposure to airborne endotoxin is a concern in occupational settings with high concentrations of organic dusts (e.g. cotton-processing facilities, agricultural settings) and industrial environments with water-spray components (e.g. machining fluids) (Gordon 1992). Airborne endotoxin is also a concern in indoor environments with humidified mechanical air-conditioning systems (Dutkiewicz et al. 1988; Flaherty et al. 1984), and the presence of dogs, moisture, and settled dust increases the likelihood of airborne endotoxin in the home (Park et al. 2001).

Symptoms of chest tightness, cough, shortness of breath, fever, and wheezing have been reported by individuals exposed to airborne endotoxin in industrial and agricultural settings (Donham et al. 1984; Lundholm and Rylander 1980; Thelin et al. 1984). Kline et al. (1999) report airflow obstruction and exacerbation of asthma related to airborne endotoxin concentration. Atopic and nonatopic asthma have been associated with endotoxin exposure because of its ability to induce inflammatory reactions (Michel 1999), and repeated inhalation exposure has been shown to induce allergen-specific airway inflammation (Wan et al. 2000). However, childhood exposure to endotoxin in a rural farm setting has been shown to provide some protection from the development of atopic childhood diseases (von Mutius et al. 2000)

Gram-positive nonspore-forming bacteria

Airborne *Staphylococcus* spp. and *Micrococcus* spp. are nonendospore-forming bacteria that are commonly disseminated from the skin, oral and nasal surfaces, and hair of humans (Favero et al. 1966). The presence of these cells in the air increases the likelihood of nosocomial infections in healthcare settings (Schall 1991). Antibiotic-resistant gram-positive bacteria in hospital environments are transmitted among patients through aerosol dispersal from inanimate surfaces, patients, and staff members (Shiomori et al. 2001). Airborne dispersal of pathogens is also a concern in home-care and assisted-living environments, where infection-control practices may not be strictly followed. Actinomycetes are filamentous nonendospore-forming gram-positive bacteria that have been associated with illness in occupants of water-damaged buildings (Hyvarinen et al. 2002). Their presence is reported in association with numerous fungi that colonize following water intrusion and colonization on building materials and furnishings, and concentrations of 10^4 CFU/m^3 have been reported during repair of damaged structures (Rautiala et al. 1996).

Bioterrorism

The threat of purposeful aerosol release of pathogenic bacteria and bacterial toxins as weapons of mass destruction (WMD) has increased the awareness of governmental agencies, the medical community, and the public of the importance of bioaerosols (Sheeran 2002). Several pathogenic bacteria have been listed as possible bioaerosol WMDs, including *Francisella tularensis*, *Yersinia pestis*, and *Bacillus anthracis*, the causative agents of tularemia, plague, and anthrax, respectively. An alert public-health system is needed to recognize these diseases and minimize exposure of the public (Dennis et al. 2001), and additional research is needed to evaluate the risk of exposed populations (Dull et al. 2002).

MONITORING FOR AIRBORNE BACTERIA

Routine monitoring for airborne bacteria is performed in pharmaceutical and food-industry settings, but

monitoring surveys in indoor environments are generally conducted in response to: (1) physician documented illness linked to occupancy of building; (2) visual evidence of biological contamination; (3) occupant complaints after a water damage incident; or (4) occupant complaints that are suggestive of biological contamination. However, documentation of bacteria in the air or on surfaces does not prove that they are responsible for disease in building occupants. Serologic tests or other diagnostic methods may be needed to directly correlate exposure with disease.

Prior to conducting the actual collection of samples, a strategy for testing should be formulated (Burge 1995) and an understanding of the water intrusion/water damage history of the building is needed (Macher 1999). Air sampling is used to document concentrations of airborne contaminants and assess exposure (Macher 1999), but air sampling alone does not provide assurance that a suspect area is free of biological contamination (Higgins et al. 2003). Cells growing on surfaces are aerosolized and settled cells become reaerosolized during routine activity (Buttner and Stetzenbach 1993; Weis et al. 2002). Therefore, surface sampling should be performed in addition to air sampling to assist in determining areas of contamination and in identifying the source of biocontamination. Surface sampling is also used in determining the effectiveness of remediation (Andersson et al. 1997; Buttner et al. 2002; Higgins et al. 2003).

Collection of airborne bacteria involves forced airflow sampling (Buttner et al. 2002). This type of sampling provides a means to determine the concentration of organisms in the bioaerosol per unit volume of air, but the specific collection method and the analysis method(s) used will influence the results. Commercially available forced airflow impaction samplers for use in the collection of bacteria deposit airborne particulate on to a semisolid agar surface. Impingement samplers collect airborne cells and other particulate into a liquid. Both impaction on to agar plates and impingement have been widely used for the collection of airborne bacteria (Buttner et al. 2002). Single-stage impactor samplers operated at 28.3 l/min for 2 min provide a lower detection limit of 18 colony forming units per cubic meter of air sampled (CFU/m^3) and an upper limit of 10^4 CFU/m^3 although at the higher concentrations considerable error is introduced as multiple cells are deposited on the same location of the agar surface. Increased sampling time beyond 3–5 min with agar-based impactor samplers results in drying of the agar surface decreasing the physical collection of airborne particles and decreasing the viability of the bacterial cells (Buttner et al. 2002). Impingement samplers collect cells in a buffered liquid. Commonly used impingement samplers designed for the collection of bacteria are operated at 10–12 l/min, but high-velocity samplers have been developed that collected larger volumes of air over extended sampling times (Radosevich et al. 2002). Collection of airborne cells into buffer permits manipulation of the sample by dilution or concentration to maximize accuracy in quantitation and affords the application of a variety of analytical methods, including culture, microscopy, immunoassay, flow cytometry, and molecular methods (Buttner et al. 2002). However, as observed with the agar-based impactors, extended sampling times may result in increased sampling stress, thereby decreasing the viability of the collected bacteria (Alvarez et al. 1994). The use of filtration sampling for monitoring of bacterial aerosols also results in dessication of bacterial cells, so this technique is generally used for sampling of airborne dust, fungal spores, and pollen (Crook 1995b). The use of settling plates or gravity sampling is not recommended for determination of airborne bacteria as it does not result in a representative sampling of airborne cell due to differential settling of particles from the air (Crook 1995a).

A variety of sampling methods have been used for the collection of surface-associated bacteria. Agar-filled replicate organism detection and counting (RODAC) with a convex sampling surface are used in hospital infection control to validate the efficacy of disinfection of surfaces. RODAC plates and agar-filled surface sampling swatches or strips are commercially available for sampling of smooth, hard surfaces in indoor environments. Sterile swabs are used to sample irregular, nonporous surfaces and they have been used to sample hard surfaces (Buttner et al. 2001; Higgins et al. 2003). Collection of settled dust in porous (e.g. carpeting, upholstery, clothing) and nonporous materials (e.g. flooring, horizontal surfaces, and furnishings) is a means to sample large surface areas and provides material for a variety of analysis methods (Macher 2001). Bulk sampling is a destructive sampling method that necessitates the removal of material from the sample site and, therefore, is used when materials are to be replaced regardless of the outcome of the monitoring (e.g. water-damaged carpet and pad, water-damaged or stained wallboard and wallpaper, and stained ceiling tile). Material collected with vacuum or bulk sampling is processed with a buffer solution containing a surfactant to assist in the separation of microorganisms from the dust and other particulates in the sample.

The agar-based impaction sampling method is limited to culture analysis. The other sampling methods can be analyzed using culture, chemical assay, and/or molecular biology. Limitations of culture-based assay include the requirement that the bacterial cells be viable/culturable at the incubation conditions and on the growth medium selected. For example, a series of media amended with antibiotics and growth factors are needed for the isolation and identification of *Legionella pneumophila* (Fields 2002), and the isolation of *Mycobacterium* species requires incubation for extended periods of time.

Stressed organisms in a bioaerosol may also require resuscitation (Crozier-Dodson and Fung 2002).

Limulus amebocyte lysate assays are used for the analysis of endotoxin (Olenchock 1990), but variations in extraction efficiency and the protocols for analysis result in differences in the results reported (Reynolds et al. 2002). A variety of analytical chemistry methods and flow cytometry can be used to identify and enumerate airborne cells (Spurny 1995). Assays for muramic acid, peptidoglycan, or fatty acids are used to detect markers of bacterial cells and endotoxin (Laitinen et al. 2001; Liu et al. 2000). Polymerase chain reaction (PCR) amplification and quantitative polymerase chain reaction (QPCR) have been shown to provide enhanced detection and rapid identification of specific airborne and surface-associated bacteria (Alvarez et al. 1994; Buttner et al. 2001; Higgins et al. 2003; Pascual et al. 2001). The use of molecular techniques requires the development of primers and probes to unique gene sequences and optimization of protocols, but the increased sensitivity and specificity of these methods, and the rapid reporting of data, provide a means to enhance the capability to monitor for contaminant airborne and surface-associated bacteria in indoor environments.

SUMMARY

Human-source and environmental bacteria can colonize and grow on a variety of indoor and outdoor surfaces when conditions are appropriate. Dispersal of bioaerosols from these surfaces and resulting exposure to bacteria and bacterial components may cause adverse human health effects. The dispersal, transport, and settling of bioaerosols is determined by physical and environmental factors, but health effects depend on the bacterial agent(s) within the aerosol and characteristics of the exposed population.

Monitoring for bioaerosols requires selection of appropriate sampling and analysis methods to determine the concentration and population of airborne bacteria and their components. Monitoring in indoor environments should also include surface sampling to determine the source(s) of bacterial contaminants. New information on human exposure to bioaerosols is being gathered with the assistance of enhanced technologies for collection and analysis, and this knowledge should provide assistance in determining risk of exposure and in understanding the fate and transport of airborne bacteria.

Bacteria as pathogens of plants and animals	8		

INTRODUCTION

Prokaryotic organisms profoundly affect virtually every facet of life on our planet. While soil- and plant-associated microbes remain unseen and underappreciated by most people, all life on Earth depends on their activities. Indeed, literally billions of years before the arrival of our first animal ancestors, prokaryotes were busy transforming Earth into the habitable planet we now enjoy. Prokaryotic autotrophs were largely responsible for the cooling of our planet by removal of CO_2 from Earth's atmosphere. The evolution of oxygenic photosynthesis in the Cyanobacteria, long before the appearance of plants, created the aerobic conditions that enabled oxygen-using higher life forms to arise. Indeed, the widely accepted theory of serial symbiosis postulates that the first eukaryotic organelles (mitochondria, chloroplasts) arose from prokaryotic symbionts (Margulis 1971). In recent years our comprehension of the abundance and diversity of the soil- and plant-associated microbiota has increased dramatically, but it is clear that good stewardship of Earth's resources will require a still deeper understanding of the microbial communities around and within us.

Microbial ecology, the study of how prokaryotes and other microorganisms interact with their physical and biotic environment, spans a number of component disciplines. Historically, methodologies for the study of soil prokaryotes have evolved in a different framework from the study of plant-associated microbes, often deriving from a different scientific perspective and with different research goals. As Paul and Clark (1989) noted, the primary thrust of soil microbiology has been on the metabolic activities of soil-inhabiting organisms, especially their roles in the biogeochemical energy flow and nutrient cycling, e.g. primary production and carbon mineralization, nitrogen fixation, nitrification and denitrification, sulfur transformations, etc. Less attention has been focused on soils as reservoirs for some animal pathogens. In contrast, approaches to the study of plant-associated microbes have tended to focus on the interspecific interactions between plants and microbes, especially the mutualistic relationships (e.g. mycorrhizae, rhizobia–legume symbioses) and the vast array of plant diseases that are of microbial origin. By definition, plant-associated prokaryotes do not lend themselves to pure culture studies, and there has been relatively less attention paid to the measurement of metabolic activity of plant-associated microbes, compared with those in soil.

SOIL AS A HABITAT FOR PROKARYOTES

Soil quality is the primary determinant of plant productivity in all terrestrial ecosystems, whether they are natural or agricultural. Soils are as much biological

entities as they are physical ones, formed by a variety of interactions that include the weathering of rock parent material, microbial autotrophic primary production, heterotrophic decomposition of plant and animal materials, and myriad mineral transformations and redistribution of materials. Viewed in cross-section, soils typically are described as series of horizons or layers (soil profile), with each layer being approximately parallel to the surface and with a unique set of characteristics. If a layer of organic litter is present it is designated the 'O' horizon; next below that is the 'A' horizon, which represents a zone where plant residues accumulate, and from which materials leach downwards. Below that is the 'B' horizon, which is a zone of accumulation of minerals and humic materials, but typically containing less total organic matter than the A horizon. Finally, the lower 'C' horizon consists of unconsolidated parent material and geologic deposits. There are a number of variations and subdivisions of the above classification scheme, which taken together (and with additional characteristics) provide a useful taxonomy of soils. Bacteria are usually the most numerous organisms in soils, with commonly as many as 10^8–10^9 cfu/g of soil (Metting 1993). In terms of biomass, prokaryote biomass typically is similar to that of fungi in the upper horizons of aerobic soils and may exceed the biomass of plant parts in soil. Typically, prokaryote soil biomass ranges from about 300 to 3 000 kg (wet weight) per hectare (Metting 1993). Microbial biomass in general is very much lower in the lower soil horizons but is dominated by prokaryotic organisms.

A variety of properties determine the suitability of a soil as a microbial habitat. These include, but are not limited to, texture, structure, water content, aeration, pH, mineral nutrient content, and soil organic matter (SOM) content. It is important to realize that each of these properties typically is discontinuous in space, often at a scale of only millimeters or even micrometers. The term 'soil texture' refers to the relative proportions of the three inorganic particulate constituents of soil: clay, silt, and sand. The sand and silt components of soil are relatively large and chemically inert, and by themselves are not sites of significant microbial activity. The nonliving colloidal materials in soil (particles less than 2 μm in size) consist of inorganic clay minerals, composed of aluminosilicate layers, as well as organic humic materials. These colloidal materials have a profound effect on microbial activity. Clay particles may have as much as 8×10^6 cm^2 of surface area per gram, compared with approximately 450 cm^2/g for silt particles and 20 cm^2/g for coarse sand. While the layers of so-called 1:1 clays (consisting of silica + alumina layers) are held together by hydrogen bonds, the layers of 2:1 clays (silica + alumina + silica) are not tightly held together, and thus these clays are highly expandable when water is present and water molecules are interspersed between the layers. Thus, the 2:1 clays have potentially much greater reactive surface area than the 1:1 clays. This is critical for chemical activity at clay surfaces, including microbial biochemical activity, because the negatively charged surfaces of clay minerals are sites of active cation exchange and repulsion of anionic molecules. Humus represents the organic colloidal component of soils; it consists of organic molecules that originated from living organisms but that have been biochemically modified and are no longer recognizable. Humic materials, like clays, have a net negative charge and high cation-exchange capacity (CEC), which enhances their interactions with synthetic organic compounds, metals, nutrients, as well as bacteria.

Soil structure, which is critical to below-ground air and water movement, water-holding capacity, and soil stability, occurs through the formation and spatial arrangement of aggregates. Soil bacteria contribute greatly to soil structure through their production of extracellular polysaccharides and other cementing compounds that help hold aggregates together, although these same compounds may also damage structure by blocking pore spaces. The majority of active bacteria are adsorbed on to particle surfaces in soil or are located at gas–liquid interfaces. Adsorption on to particles provides some degree of protection from predation by protozoa and soil arthropods, and it also places the bacterial cells in close proximity to adsorbed mineral nutrients. Additionally, extracellular enzymes produced by the bacteria also may be adsorbed nearby, so that the products of those enzymes will be more readily available for absorption, rather than being lost by diffusion into the soil solution. It should be remembered that prokaryotes are primarily aquatic organisms, and that at the prokaryote scale, soils often are functionally aquatic habitats. About 30 percent of the volume of a typical well-drained soil is in the liquid phase with another 20 percent in the gaseous phase and the remaining 50 percent as solids. Water in a well-drained soil typically is discontinuous, and its distribution is a function of the soil pore size distribution as determined by soil texture and structure. Through their effects on soil structure, bacteria effectively determine much of their surrounding physical environment. Aerobic and facultative aerobic bacteria also play a role in the spatial distribution of oxygen within and around soil aggregates. Oxygen diffuses only slowly through water, so that water-filled pores form effective seals around portions of aggregates, and oxygen within those zones may be depleted by aerobic respiratory activity and then maintained at low levels by the scavenging of oxygen by facultative anaerobes. In this way, anaerobic microsites are formed and maintained, even in otherwise well-aerated soils. Facultative anaerobes and even strict anaerobes can thus be active within aerated soils, and important anaerobic processes (e.g. denitrification) can take place in these microsites. Even under conditions where microsites become oxic, strict anaerobes may be able to persist

although active growth will not occur. There are two basic ways that strict anaerobes may survive oxic conditions: first, a number of strict anaerobes, for example *Clostridium* spp., form dormant spores. Also, vegetative dormancy may allow cells of a strictly anaerobic species to survive oxic periods. The compounds hydrogen peroxide and superoxide are byproducts of certain oxygen-utilizing reactions, and these compounds are destructive to cells. Aerobic organisms have enzymes that destroy these agents, for example the enzymes superoxide dismutase (which converts superoxide to the products O_2 and H_2O_2) and catalase (which then converts H_2O_2 to water and oxygen). Strict anaerobes lack these enzyme systems; however, because the toxic byproducts are only formed during active metabolism, physiologically dormant anaerobes may escape their effects.

PLANT-ASSOCIATED PROKARYOTES

The metabolic activity of soil bacteria contributes greatly to a soil's fertility and its ability to support plant growth. In turn, plant residues and root exudates are the most important food source for the free-living heterotrophic microbial populations in soils. Also, plant surfaces and interiors are themselves important habitats for microorganisms, and nutrients leaking from aerial plant parts support considerable microbial growth on plant surfaces. Indeed, some microorganisms are able to grow only in association with plants. I will use the terms 'rhizosphere' and 'phyllosphere' as nouns to describe plant-associated habitats and as adjectives to describe the microbial components of those habitats.

The rhizosphere

The term 'rhizosphere' was first used by Hiltner (1904) to describe the interaction between bacteria and the roots of legumes. A somewhat analogous term, 'spermosphere,' refers to the area of increased microbial activity around a seed. Organic and inorganic materials released from roots, leaves, and seeds are important determinants of microbial activity, numbers, and interactions on plant surfaces and in the adjacent soil. In turn, the plant-associated microbial community strongly influences plant health and productivity. Typically, the rhizosphere may extend up to 5 mm or slightly more away from the root surface. As Lynch (1987) noted, the rhizosphere environment actually is comprised of the interacting plant, adjacent soil, and associated microorganisms. Microbial habitats within the rhizosphere are sometimes further classified as endorhizosphere (within the root tissue itself) or rhizoplane (on the root surface). Populations of microbes in the rhizosphere differ quantitatively and qualitatively from those in the bulk soil; their numbers are generally higher, and different populations commonly are represented. Plant roots release compounds, including simple sugars and amino acids, that encourage the growth of specific microbial communities. Because rhizosphere inhabitants rely heavily on organic exudates for their carbon and energy requirements, their metabolism may be closely tied to that of the plant (Bowen and Rovira 1976; Lynch 1987).

Although many rhizosphere microbes form apparently commensal relationships with plant roots, there are numerous well-known relationships involving mutualism and/or parasitism. Roots of many plants form an intimate relationship with certain fungi; the resulting mycorrhizal association results in enhanced uptake of certain mineral nutrients including phosphorus. Legumes and some other plants form symbioses with nitrogen-fixing bacteria. The mutualistic relationship between legumes and *Rhizobium* bacteria allows the plants to grow in otherwise nitrogen-deficient soil and enhances the soil's nitrogen status for other plants. Some microbes in the rhizosphere or phyllosphere are plant pathogens. With the exception of some vectored or seed-borne organisms, most plant pathogens first contact the plant at the phylloplane or rhizoplane. While some fungal plant pathogens are well equipped to breach these surfaces mechanically or enzymatically, many others spend much of their life cycle as nonparasitic rhizosphere or phyllosphere inhabitants and enter a parasitic phase only when conditions are conducive to passive entry and subsequent colonization of plant interiors. In contrast, some microbes in the rhizosphere or phyllosphere are antagonistic to plant pathogens or insect pests, and thus serve as potential biological control agents for agriculture and forestry.

Plant roots modify the surrounding soil environment in various ways. Almost all chemical components of the plant have been found to be lost from roots. Root deposition includes exudates that contain water-soluble compounds such as sugars, amino acids, organic acids, hormones, and vitamins, as well as sloughed whole cells and volatile compounds. It is generally believed that the zone just behind the root tip is the site of maximum root exudation. As roots elongate through soil, cells are sloughed off from the root cap, and root hairs and cortical cells are sloughed from the surface. Deposition from roots provides a readily used energy source for microbes, and spatial variation in the components of rhizodeposition over the root surface greatly influences variability in the composition of the rhizosphere community (Whipps 1990). Other plant influences on the rhizosphere community include the removal of soil water by plant uptake, release of extracellular enzymes, and reduced oxygen tension and the release of CO_2 due to aerobic respiration, with an accompanying localized increase in soil acidity. In turn, microbes associated with plant roots modify the rhizosphere environment by producing extracellular enzymes and plant growth factors and by forming parasitic or mutualistic

relationships with the plant. As a consequence, the quantities and types of available substrates in the rhizosphere differ from those in the bulk soil, resulting in different compositions of the respective microbial communities. This so-called 'rhizosphere effect' reflects the influence of plant roots on the size and composition of the surrounding soil microbial community. One numerical measure of rhizosphere effect is the R/S (rhizosphere/soil) ratio, which compares the total number of microbes in a rhizosphere habitat with the number in the root-free soil. R/S ratios range from as low as 5 to 100 or more but most frequently are from 10 to 20 (Curl and Truelove 1986; Gray and Parkinson 1968; Katznelson 1965). Absolute size estimates of the rhizosphere vary greatly, depending in part on the plant species and spatial location on the root, which is reflective of physiological maturity (Darbyshire and Greaves 1970) as well as soil temperature and moisture content.

The phyllosphere

Aerial plant parts, both surfaces and interiors, are important habitats for bacteria and support both autochthonous and allocthonous microbial populations. The term 'phyllosphere' has a similar etymology to the term 'rhizosphere' and has been applied to the habitats including plant interiors (also called the endophytic habitat) as well as plant surfaces (sometimes referred to as the phylloplane). Microorganisms colonizing the aerial parts of plants are sometimes called epiphytic microbes (from the Greek, *epi* [on top of] and *phytos* [plant]), but unlike the epiphytic plants that derive no nutrition from the plant surfaces they inhabit, epiphytic microbes actively utilize compounds exuded from leaves and other aerial plant parts. In the tropics, species of nitrogen-fixing bacteria are important inhabitants of foliar surfaces. Although noncolonizing (allocthonous) microbes frequently can be found in the phyllosphere, there is substantial evidence of defined microbial succession and the development of specific phyllosphere communities (Blakeman 1981). On new leaves, bacteria predominate in the microbial community, while yeasts and filamentous fungi succeed them and become dominant later in the growing season (Kinkel 1991; Kinkel et al. 1987). The important environmental factors impacting phyllosphere populations include ambient and leaf surface temperature, relative humidity and leaf wetness, and solar radiation. Leaf surfaces can be harsh habitats, since microbes on them are exposed to radiation and the dessicating effects of wind and sunlight, yet populations of 10^6 or more bacteria per square centimeter of leaf surface may be supported. Generally, environmental factors fluctuate more rapidly in the phyllosphere than in soil, so that microbial numbers can differ greatly even between samples taken over a short time period.

With the exception of Cyanobacteria (which are able to fix both C and N) on the foliar surfaces of some tropical plants, plant foliar leachates serve as the primary source of carbon and mineral nutrients for epiphytic bacteria. These leachates include a variety of sugars, organic acids, and amino acids, and their transfer from the leaf interior to the leaf surface takes place via aqueous pores (Blakeman and Atkinson 1981; Tukey 1971). Some epiphytic bacteria may themselves increase leaf wettability by the production of biosurfactant compounds (Bunster et al. 1989). Many epiphytic bacteria appear to be commensals and do not harm the plant upon which they reside. However, aerial plant surfaces may be successfully colonized by virulent strains of phytopathogenic bacteria, as well as by nonpathogenic isolates of the same or related species (Hirano and Upper 1983).

Bacteria in several genera, whether naturally occurring or modified by recombinant DNA techniques, offer promise for foliar application to crops for control of insect pests, plant pathogens, and weeds, or to protect plants from frost injury (e.g. Armstrong et al. 1987; Blakeman and Atkinson 1981; Knudsen and Hudler 1987; Lindow et al. 1988). Research on microbial pest-control agents for foliar application has progressed to where field tests are needed to evaluate their performance. The first genetically engineered microorganisms to be released legally in the USA were strains of *Pseudomonas syringae* and *P. fluorescens* from which the ice nucleation gene was deleted; these were intended to competitively exclude indigenous ice nucleation-active bacteria involved in frost damage. Small-scale field releases of aerosolized ice-nucleation-minus bacteria were undertaken by the University of California at Berkeley, and there was a large investment in time, money, and effort in attempts to determine dispersal patterns and survival of the applied bacteria (Knudsen 1988; Lindow et al. 1988). Concerns about possible environmental effects of genetically engineered microorganisms applied to crop plants include uncertainty about their dispersal, survival, and interactions with indigenous organisms, and this interest has fueled much of the recent research on epiphytic bacteria.

Soil, the rhizosphere, and the phyllosphere are populated by complex communities of organisms, including microbes (bacteria, Archaea, fungi, Protists) but also typically including plant and animal components. The rhizosphere and phyllosphere are defined by the presence of a plant, so it is inherently impossible to characterize microbial activity in these habitats through the study of genetically uniform microbial strains in isolation. Determining microbial contributions to these communities may require a variety of techniques with different areas of focus. For example, it has long been known that microbes may be metabolically active even though they are not culturable (Colwell et al. 1985). Furthermore, quantification of the viable microbial

biomass may help elucidate the potential for specific microbial metabolic activities in a particular habitat, but the nonviable biomass may also be important as a component of the food web, despite its lack of a direct metabolic contribution. Although it is possible and common to make inferences about microbial biomass based on microbial community metabolic activity, it is important to note that these may not be strongly correlated, i.e. high metabolic activity does not necessarily mean an actively growing, dividing microbial community. Also, it is important to remember that microbial physiological activities are often strongly affected by the physical arrangement of the members of a population, especially aggregations such as those that occur in biofilms, on root surfaces, and in soil microsites. Physiological and spatial heterogeneity have important implications for the ecology of microbial populations and communities, and the ability of recently developed molecular and microscopic methods to address heterogeneity in environmental samples is especially exciting.

There has been an explosion of interest in the subject of microbial biofilms in recent years. The majority of microbes in natural ecosystems are not free-floating (planktonic) but instead typically grow attached to surfaces and encased in an adhesive, usually a polysaccharide material, forming complex communities called biofilms (Costerton et al. 1986). Bacteria on plant surfaces such as leaves and roots may form biofilms, and development of plant-surface biofilm communities and regulation of biofilm polysaccharide production has been studied for several root-colonizing bacteria (e.g. Hax and Golladay, 1993; O'Toole and Kolter 1998; Sarand et al. 1998). There is great potential for the use of biofilm bacterial communities on plant roots for bioremediation of soil pollutants (Yee et al. 1998). Techniques used to investigate root biofilm communities have included confocal microscopy with or without targeted ribosomal DNA (rDNA) probing, scanning electron microscopy (SEM) and transmission electron microscopy (TEM), and polymerase chain reaction (PCR)-assisted rDNA restriction fragment length polymorphism (RFLP)/sequence analyses.

BIOGEOCHEMICAL TRANSFORMATIONS BY SOIL- AND PLANT-ASSOCIATED PROKARYOTES

Largely unheralded by humans, the Bacteria, Archaea, and Fungi drive the biogeochemical cycles that make this planet habitable for plants and animals. Entire volumes detail the roles of the prokaryotes in carbon fixation and decomposition or organic compounds, in the cycling of nitrogen, sulfur, phosphorus, and other elements essential to life, and in transformations of metals. We have only started to understand and appreciate the astounding degradative capacity of the prokaryotes and to apply it to remediation of natural and man-made environmental pollutants. Below is a short summary of a few of the major biogeochemical roles that prokaryotes play.

Prokaryote contributions to carbon cycling

Availability of mineral nutrients is an important limitation for most bacteria in soil and on plant surfaces. Available carbon typically is less limiting. Heterotrophy, which is the utilization of fixed organic substrates as a carbon source, is the dominant lifestyle for most soil- and plant-associated prokaryotes. The autotrophic representatives of these habitats (i.e. those organisms that are able to fix CO_2 or carbonates for their carbon needs) include relatively small numbers of the photoautotrophic Cyanobacteria, which inhabit some surfaces that are exposed to light (e.g. some soil and plant surfaces, swampy soils, and exposed surfaces as cosymbionts with ascomycetous fungi in lichens). Several chemoautotrophs are present in soils, most significantly the nitrate- and nitrite-oxidizing nitrifiers, as well as those bacteria that aerobically oxidize reduced forms of sulfur, iron, or manganese for their energy needs. Methanogens, which are members of the Archaea, are able to fix CO_2 and/or carbonates and are important in anaerobic sediments. However, the overall contribution of microbial autotrophy to the carbon balance of soil or plant habitats is relatively minor compared with the importance of heterotrophic decomposition of plant (and animal) materials. Within the constraints of mineral nutrient availability, especially nitrogen, heterotrophic bacteria in soil quickly colonize any organic matter that is added. Because bacteria are generally limited to the surfaces of organic particles, the size of particles (i.e. surface to volume ratio) is critical in determining the extent that this resource can be exploited. Soil arthropods can play an important role here, as their feeding activity shreds and mixes the plant litter, thus exposing it to bacterial activity. Arthropods may also increase available nitrogen by excreting uric acid.

Many bacteria escape limitations imposed by lack of nutrients by dormancy, either in the vegetative state or as spores. When a nutritional source becomes available in soil, typically there is a temporal succession of microbes that are able to utilize the resource, as the quality of the available substrates changes during decomposition. Those first able to colonize the resource usually are r-selected (Andrews and Harris 1986) bacteria such as *Bacillus* and *Pseudomonas*, as well as fungi such as *Penicillium* spp., which are able to rapidly utilize available sugars and amino acids. They are followed by a variety of K-selected (Andrews and Harris 1986) organisms that include prokaryotes such as Cyanobacteria but also a number of fungi. Many of these late-succession organisms either are stress-tolerant or possess

highly competitive mechanisms such as cellulose- or lignin-degrading enzyme systems. Production of antibiotic compounds may also play a role in competition among soil microorganisms, although production of antibiotics in situ, as well as its ecological significance, have been difficult to demonstrate (Williams 1986). Only relatively recently has antibiotic production in soil been definitively shown to occur (Thomashow and Weller 1991), and it is possible that the level of antibiotics is still very low because of adsorption to clay minerals and humic materials. Many of the antibiotics that are so important in the treatment of infectious diseases in medical and veterinary practice, derive from soil microbes, especially the Actinomycetes.

Prokaryote contributions to nitrogen cycling

Nitrogen is a critical element for all forms of life. It is a building block of nucleic acids as well as amino acids, and thus is a major component of the genetics, physiological activity, and structural integrity of all organisms. Although the cellulose and lignin molecules that provide structural rigidity to plants are free of nitrogen, it still is the fourth most abundant element in plant composition, after C, H, and O. It is the mineral nutrient that most often is limiting for plant nutrition. Nitrogen is a cell-wall component of the majority of microbes, part of the chitin molecule found in the higher fungi, and the peptidoglycan molecule found in bacterial cell walls. The ratio of carbon to nitrogen varies among microorganisms, but generally it is significantly lower than in plants or in soil. Typical C:N ratios of fungi range from about 4.5:1 to 15:1, and for bacteria it usually is even lower, in the range of 3:1 to 5:1. By way of comparison, the C:N ratio in a typical arable soil is about 10:1, about 25:1 in green-plant material, and as much as 100:1 in dried plant residues such as straw. For this reason, nitrogen availability is usually limiting when plant materials are being decomposed in soil. The microbiota quickly mineralizes the nitrogen that is present in plant residues and immobilizes much of it in the form of microbial biomass.

Along with its occurrence as a component of organic molecules, the N atom can be found in a number of different inorganic molecules of differing oxidation states. Microbes mediate most of the transitions between these states and thus play essential roles in nitrogen cycling. The NH_4^+ (ammonium) form is the product of microbial mineralization of organic nitrogen compounds in soil and is readily assimilated by both plants and microorganisms. Because it is a cation, the ammonium ion may attach to negatively charged clay minerals and become entrapped or 'fixed' between the layers. This process, ammonium fixation, should not be confused with dinitrogen fixation, which is the transition (most commonly microbially mediated) of atmospheric N_2 into ammonia and subsequently to organic nitrogen in biological systems. Under basic soil conditions, NH_4^+ ions will be deprotonated to NH_3; this form may volatilize and be lost from soil, especially under warm and dry conditions.

The aforementioned nitrifying bacteria are aerobic autotrophs that oxidize ammonium to nitrite (NO_2^-) and then oxidize nitrite to nitrate (NO_3^-), as a source of energy. The latter step occurs readily and nitrite rarely accumulates in soil. Different autotrophic nitrifying bacteria are responsible for each of these steps, e.g. *Nitrosomonas* oxidizes ammonium to nitrite, while *Nitrobacter* oxidizes nitrite to nitrate. Heterotrophic nitrification also occurs and may be especially significant in forest soils. Although heterotrophic nitrification primarily is done by fungi, a number of aerobic bacteria have been shown to nitrify heterotrophically, including species of *Arthrobacter*, *Aerobacter*, *Mycobacterium*, *Streptomyces*, *Thosphaera*, and *Pseudomonas*. Nitrate is a preferred nitrogen source for many plants and thus nitrification may increase soil fertility. However, because NO_3^- is an anion, it is repelled by the negatively charged surfaces of clay minerals and humic materials, and thus it is highly mobile in soil solution. Nitrate leaching and movement into groundwater is a significant health and environmental problem. Excessive nitrate levels in drinking water are the cause of infant methemoglobnemia, or 'blue-baby syndrome', as the infant gut favors formation of nitrite, which in turn binds to hemoglobin and prevents it from accepting and transferring oxygen. Nitrates in drinking water are also linked to formation of carcinogenic nitrosamines. Environmentally, nitrates in groundwater provide a nitrogen input to lakes and ponds and encourage growth of algae and subsequent eutrophication of the water body.

Nitrate is also susceptible to loss from soil through the process of denitrification, in which various facultatively anaerobic bacteria (e.g. *Pseudomonas denitrificans*, *Thiobacillus denitrificans*) utilize NO_3^- as a terminal electron acceptor in anaerobic respiration. The pathway of denitrification is: $NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$. The gaseous intermediates NO (nitric oxide) and N_2O (nitrous oxide) are always released during denitrification and are atmospheric pollutants that are involved in catalytic destruction of atmospheric ozone.

DINITROGEN FIXATION

For most plants, the direct acquisition of nitrogen is primarily from uptake of the mineral forms NH_4^+ and NO_3^-, which are derived from organic matter decomposition in soil. However, a significant amount of the nitrogen used by some plants comes directly from the biological fixation of atmospheric nitrogen (N_2). Biological nitrogen fixation, which is the conversion of atmospheric dinitrogen to ammonia, is mediated by the nitrogenase enzyme system, which is unique to prokaryotes. A number of free-living and plant-associated

bacteria fix nitrogen in terrestrial ecosystems. Approximately two-thirds of all the nitrogen fixed globally is through biological dinitrogen fixation.

Nitrogen fixation requires relatively large amounts of energy, either in the form of light energy for the phototrophic Cyanobacteria or as energy stored in the chemical bonds of organic compounds for the heterotrophic nitrogen-fixing bacteria. The symbiotic association with plants is valuable for associative nitrogen-fixers for this reason, and the symbiotic legume–rhizobia and alder–*Frankia* associations are thus especially effective and important in the amount of nitrogen they fix on a global basis. The legume–rhizobia and alder–*Frankia* associations are examples of mutualism, and both partners clearly benefit from the association. In each case, root nodules are formed containing the bacteria, which are only able to fix nitrogen in association with the plant host. Nodule formation is a complex process involving a series of physical and chemical interactions beween the symbiotic partners.

Certain Cyanobacteria also partner with ascomycetous fungi to form lichens, which are common in terrestrial habitats. The prokaryote partner in this mutualistic association is able to fix not only nitrogen but carbon as well, through photosynthesis, while the eukaryote partner obtains mineral nutrients from the substratum. The association allows lichens to thrive in austere habitats such as the surface of rocks, where both organic carbon and mineral nitrogen are extremely limited. Significant amounts of nitrogen are also fixed by free-living bacteria in a variety of habitats, including associated with plant roots (e.g. *Azospirillum* and roots of grasses) or foliage, the latter especially in the tropics. Tropical epiphytic microbial communities are made up of a number of taxonomic groups, including several genera of nitrogen-fixing bacteria, such as *Azotobacter*, *Beijerinckii*, *Klebsiella*, and Cyanobacteria such as *Nostoc* and *Scytonema*.

Prokaryote transformations of sulfur

A variety of primarily chemoautrophic and chemoheterotrophic prokaryotes are responsible for oxidizing sulfur in soils, under aerobic conditions. The most well known genus is *Thiobacillus*, which is found in a variety of habitats (one species, *T. denitrificans*, is also capable of anaerobic growth, using nitrate as a terminal electron acceptor). The phototrophic purple sulfur and green sulfur bacteria, which are dominant sulfur oxidizers in aquatic systems, are mostly absent from soil habitats due to their simultaneous requirements of light and anoxic conditions. However, they may be found in aquatic–soil interfaces, such as rice paddies and wetlands. *Sulfolobus*, a member of the Archaea, is an important sulfur oxidizer, especially in thermal habitats, but its importance in most soils is largely unknown. Soil microbes reduce sulfur compounds in an assimilatory process to meet their sulfur needs. Dissimilatory reduction of sulfate to hydrogen sulfide, by organisms using sulfate as a terminal electron acceptor, occurs primarily in aquatic sediments but also may be significant in anaerobic, waterlogged soils and possibly in anaerobic soil microsites. Release of H_2S by sulfate reducers such as *Desulfovibrio* spp., *Desulfomonas* spp., and *Desulfomaculatum* spp., provides an energy source for nearby sulfur oxidizers in tightly linked microbial communities.

BIOTRANSFORMATION AND BIOREMEDIATION

In the very early twentieth century, the great microbial ecologist Martinus Beijerinck made his famous statement, 'Everything is everywhere, the environment selects.' Beijerinck recognized that microbes and the vast diversity of their metabolic capabilities are almost ubiquitous in the environment and that environmental influences select for certain microbial types. A variety of environmental pollutants are naturally occurring, nonsynthetic materials, such as petroleum products, nitrates, heavy metals, and acid mine drainage. In the latter part of the twentieth century, scientists became more aware of the prescience of Beijerinck's comments, as microbes in natural habitats were observed to successfully degrade a wide range of pollutants. The list of compounds that bacteria may successfully degrade in the environment includes petroleum or hydrocarbon products such as gasoline, diesel, and fuel oil, hazardous crude oil compounds such as benzene, toluene, xylene, and naphthalene, certain polynuclear aromatic compounds, certain pesticides (e.g. the insecticide malathion), coal compounds, some industrial solvents such as acetone, as well as ethers, methanol, methylethylketone, and ethylene glycol.

However, it was soon realized that a large number of organic chemicals synthesized by humans, which we now call 'xenobiotics,' have no close natural chemical analogs and often are able to persist in the environment because appropriate transport mechanisms and catabolic pathways have not evolved in natural microbial communities. Xenobiotic compounds include a number of pesticides and products generated from them, many plastics, industrial chemicals, and manufacturing byproducts, and compounds newly formed in nature from synthetic components. Typically, xenobiotic compounds are not found individually, but rather in simple or complex mixtures. Many of these compounds are toxic at low concentrations, and some are subject to biomagnification through the food chain. The potential for biodegradation of xenobiotic compounds is a subject of intense research. Fortunately, while a number of xenobiotic compounds may not support the growth of any single microorganism, they may nonetheless be degraded in the presence of other natural substrates, a process that is known as cometabolism. Also, a number of xenobiotics

may be degraded through the cooperative efforts of several microbial strains comprising a microbial consortium.

The term 'bioremediation' refers to a variety of technologies that rely on the biodegradative capabilities of microorganisms for the mineralization or inactivation of chemical pollutants in contaminated sites. Complete mineralization, i.e. decomposition of a pollutant to inorganic ions and CO_2, is the most desirable situation because the end products are usually nontoxic. Although soil may be removed and transported from a site for ex situ bioremediation, this usually is prohibitively expensive, and in situ bioremediation (ISB) is the norm. There are two general approaches to bioremediation. The first, sometimes called 'bioaugmentation,' is intended to enhance the degradative potential of microbes already present at the site, by environmental modifications including nutrient application, aeration, mixing, etc. A second approach involves addition of appropriate xenobiotic degraders by seeding. Ideally, bacteria chosen as agents for bioremediation of organic pollutants will have a number of characteristics beyond the ability to digest the particular waste material rapidly and completely; these include the nonproduction of odors or noxious gases, nonpathogenicity to humans or other animals, and competitive ability in the natural environment. For some pollutants, commercial strains of bacteria and fungi have become available. These strains have been selected or in some cases genetically engineered for specific degradative capabilities.

BACTERIA AS PATHOGENS OF PLANTS AND ANIMALS

Despite the fact that prokaryotes are absolutely essential in making our planet a habitable place for plants and animals, most people still are most familiar with the small group of usually specialized bacteria that are pathogenic to humans, other animals, and the crops we grow for food and fiber.

Phytopathogenic bacteria

While the number of plant diseases caused by bacteria is smaller than those caused by fungal pathogens, nonetheless soil-borne and foliar bacterial plant pathogens are responsible for a large number of plant diseases, including various wilts, blights, galls, leafspots, and rots. The taxonomy of phytobacteriology is evolving continually, but pathogens are found in the genera *Pseudomonas*, *Burkholderia*, *Xanthomonas*, *Streptomyces*, *Agrobacterium*, *Erwinia*, *Corynebacterium*, and *Spiroplasma*. Some are obligate pathogens and many are seed-borne. A large number are saprophytic and capable of surviving and reproducing in soil. Pseudomonads especially are common and abundant in soil and the rhizosphere. A number of fluorescent pseudomonads have a permanent soil phase. Xanthomonads, some *Erwinia* spp., and a number of pseudomonads are associated with above-ground plant surfaces and can cause a number of serious foliar diseases. *Pseudomonas syringae*, for example, is responsible for a number of economically significant diseases of vegetables, fruits, and ornamentals.

Phytopathogenic bacteria gain entrance into plants through wounds or natural openings, which include stomata, lenticels, hydathodes, and nectarthodes. Once bacterial cells gain entrance into the plant, they may biochemically elicit plant-defense responses. The recognition phenomena that govern these responses typically are quite specific and are determinants of whether a particular bacterial strain is pathogenic. A number of virulence determinants are encoded by the pathogen genome, and govern the pathogen's 'weapons,' which may include toxins, hormones, extracellular polysaccharides, and enzymes such as cellulases and pectinases that are involved in degradation of plant cell walls.

One unique soil-borne plant pathogen that has proven to be of immense utility is the bacterium *Agrobacterium tumefaciens*, the causal agent of crown gall disease. *Agrobacterium* is a relatively common genus in soils, and the pathogen *A. tumefaciens* is easily disseminated by farm machinery, tools, irrigation, or rain-splashed soil. The pathogen gains entry through wounds and colonizes the wounded plant tissues. Then, a portion of the pathogen's own DNA in the form of a plasmid (Ti plasmid, for 'tumor-inducing') enters into a living host cell and somehow gains entry into the host nucleus. The newly introduced pathogen genes code for production of growth hormones, and large woody galls are formed on the plant roots (or, in some cases, plant stems). The galls form a highly nutritive environment for the pathogen, but the hypertrophic growth may result in collapse of plant vascular tissue and death of the host. Eventually, bacteria are released from decaying galls into surrounding soil or water. The ability of a prokaryotic organism to transfer some of its own DNA into the genome of a eukaryotic host is a unique characteristic. Plant molecular biologists have taken advantage of this ability, by generating variants of *A. tumefaciens* that are able to transfer DNA without the genes required to incite galls in the host plant. A wide variety of genes have been inserted into the bacterial plasmid, allowing plants to be transformed with any number of desirable traits.

Bacteria as biological control agents against plant pathogens

Many or most bacteria associated with the exterior surfaces of plants are nonpathogenic. Among those are a number of organisms that have been found to be

antagonistic to bacterial and fungal plant pathogens, thus potentially acting as biological control (biocontrol) agents. Biological control may be defined as the use of one organism to suppress another organism that is an agronomic pest or parasite, or that is environmentally injurious. A number of mechanisms have been implicated in biological control of plant pathogens by beneficial bacteria, including production of antibiotic compounds, nutrient competition, hyperparasitism, and stimulation of host defenses. A variety of rhizosphere bacteria, which are effective colonizers of plant roots, have been designated plant growth-promoting rhizobacteria (PGPR). A number of PGPR have been identified, and several of these are being promoted as plant-disease-control products (Bahme and Schroth 1987; Kloepper and Beauchamp 1992; Suslow and Schroth 1982). Organisms that have received a great deal of attention include strains of *Pseudomonas fluorescens*, *Bacillus subtilis*, and *Streptomyces griseoviridis*, and they are being used especially for protection of high-value crops, including bedding plants, foliage plants, ornamentals, and some vegetable crops.

Soil- and plant-associated animal pathogens

Humans and other animals generally play a minor role as habitats for bacteria, but the effects on animal populations nonetheless can be devastating. A number of pathogenic prokaryotes are normally soil inhabitants but are facultative parasites of animals. Thus, soil (and to a lesser extent, plants) can serve as a reservoir for these bacterial pathogens.

Pathogens of medical and veterinary significance

Several important animal diseases are caused by pathogens that are indigenous to soil or plant surfaces. Some of the most important causal agents are spore-forming bacteria in the genera *Bacillus* and *Clostridium*, in part because of their ability to survive adverse environmental conditions. Anthrax is an acute infectious disease caused by the aerobic spore-forming bacterium *Bacillus anthracis*. Anthrax most commonly occurs in wild and domestic vertebrates (cattle, sheep, goats, camels, antelopes, and other herbivores), but it can also occur in humans when they are exposed to infected animals or tissue from infected animals. The anthrax organism is endemic in many agricultural regions throughout the world, including South and Central America, Southern and Eastern Europe, Asia, Africa, the Caribbean, and the Middle East. Horses, swine, deer, and humans are less susceptible than are cattle or sheep. Wild ruminants such as deer also may become infected. Infection in ruminants or horses is usually the result of grazing on infected pasture land. The organisms typically enter through the mouth, and less commonly via skin injury. After ingestion or inhalation, the bacteria spread rapidly throughout the body. Anthrax disease in humans typically results from occupational exposure to infected animals or by inhaling anthrax spores from contaminated animal products. Anthrax has become a major public-health issue because *B. anthracis* is considered to be a potential agent for use in biological warfare.

Members of the genus *Clostridium* are also spore-forming bacteria, but they are strict anaerobes. Clostridium is responsible for a number of important animal diseases, including blackleg of cattle and sheep (*C. chauvoei*), red-water disease of cattle (*C. haemolyticum*), enterotoxemias of various mammals caused by *C. perfringens*, botulism of cattle, horses, sheep, and occasionally humans (*C. botulinum*), and tetanus (all mammals) caused by *C. tetani*.

Clostridia are found naturally in soil, aquatic sediments, and animal gastrointestinal tracts. The majority are not pathogenic to animals, and species are significant for their ability to fix nitrogen. *Clostridium perfringens* causes gas gangrene disease, which results from contamination of wounds with soil containing spores of the bacterium. Clostridial food poisoning (botulism) results from eating food that is contaminated with soil or feces containing *C. botulinum*, and which then is stored under anaerobic conditions that permit reproduction of the organism. All forms of botulism can be fatal, although the disease is relatively rare. A number of other genera of soil bacteria, especially gram-negative bacteria in the genera *Pseudomonas*, *Enterobacter*, and *Acinetobacter*, may be of medical importance.

A number of plant- and soil-associated bacteria are pathogens of arthropods, including a number of insect pests. Many, like the gram-negative bacterium *Serratia marcescens*, are facultative parasites that, once ingested, may be able to invade the hemocoel if the integrity of the gut lining is compromised. Two members of the genus *Bacillus* have been widely used as microbial insecticides against a number of important insect pests. *Bacillus popilliae* causes 'milky-spore disease' of beetle larvae in soil. Larvae that ingest spores of this organism cease feeding, turn milky white in color from the profuse sporulation of the bacterium in the hemocoel, and then die. *Bacillus popilliae* has been commercialized and is widely used against Japanese beetle in lawns and turfgrass. More well known is the related organism, *B. thuringiensis*, which is arguably the most successful biological control agent in history. Along with spore formation, *B. thuringiensis* produces a parasporal crystalline protein. The organism is primarily an inhabitant of soil, but it is used primarily for foliar application as a biocontrol agent. When the crystalline protein, also known as the δ-endotoxin, is ingested by the herbivorous larvae of lepidopteran pests, it dissolves in the alkaline

gut of the insect. The toxin disrupts the membranes lining the gut, and septicemia may follow as bacteria proliferate in the hemocoel. The larvae soon stop feeding and die soon thereafter. The organism is easily grown in mass culture, dried, and culture residues containing spores and crystals formulated for spraying on crops and forests. There are several commercial Bt formulations currently on the market, and certain subspecies of the organism have demonstrated efficacy against coleopteran (beetle) and dipteran (flies, including mosquitoes) pests. More recently, the toxigenic gene of Bt has been placed into strains of *Pseudomonas fluorescens* for use as seed or root inoculants, and into the maize endophyte *Clavibacter pyli* for protection against the European corn borer. Genes for toxin production have been inserted directly into crop plants via genetic engineering, and crops with Bt genes are now widely used in commercial agriculture. This approach is controversial, however, as it exerts a strong selection pressure on the pest population to develop Bt resistance. Resistance has already been observed in some important pest species, such as Colorado potato beetle.

Recombinant bacteria

Along with examples noted above, a number of soil- and plant-associated bacteria are candidates for genetic engineering, in order to enhance their environmental fitness or biological control efficacy. Environmental release of engineered bacteria has raised concerns about the possible spread of recombinant DNA sequences to other organisms present in the same environment. Bacterial plasmids and transposons occur in most prokaryotes; they carry the genetic determinants of many important phenotypic properties including antibiotic and heavy metal resistance, production of antibiotics, bacteriocins, and toxins, catabolism of xenobiotic compounds, nodulation and nitrogen fixation, plant tumorigenesis, and insecticidal toxin production. Knowledge about the potential of introduced organisms to transfer genetic information to other bacteria present in a given habitat is essential for assessment of possible environmental risk.

SAMPLING AND DETECTION METHODS FOR SOIL- AND PLANT-ASSOCIATED PROKARYOTES

A wide array of traditional and novel methods is now available to investigate the activities of microbes in soil and plant habitats. Particularly exciting advances have been made in our ability to observe, in situ, many aspects of microbial physiology that previously could only be demonstrated with pure cultures under highly controlled conditions. Various new strategies are available for detection of bacteria, their genes, and their gene products in natural environments. These strategies are equally useful for tracking the fate of introduced organisms and their genetic information in soil and the rhizosphere.

There are two general approaches to the quantitative estimation of microbial populations in the rhizosphere or phyllosphere: direct methods such as visualization techniques, and indirect methods such as dilution plating of root or leaf washings, or most probable number (MPN) estimates (Cochran 1950). Indirect methods have been reported to recover only about 0.01–10 percent of the numbers of bacteria enumerated by direct counts (Campbell and Porter 1982; Colwell et al. 1985; Richaume et al. 1993). However, direct counts are difficult to obtain from an opaque medium such as soil. Also, they may overestimate the number of bacteria in soil because it is difficult to differentiate between living and dead cells unless using a viability stain. In addition, a high level of concentration is needed by the observer; direct counts are labor-intensive if large numbers of samples need to be processed. Another disadvantage with direct counts is that different groups of organisms are difficult to identify unless their morphologies differ. Since precise identification of what constitutes rhizosphere soil is difficult or impossible, researchers are often forced to rely on an operational definition of the rhizosphere. In many studies, the rhizosphere has been defined as the thin layer of soil adhering to the root system after loose soil has been removed by shaking. However, depending on soil texture and moisture content, the amount of adhering soil may vary considerably. Parke et al. (1990) reported that the amount of adhering soil (from 0 to 1200 mg/cm of root) on roots and adhering soil mass (from 25 to 1000 mg) did not significantly affect estimates of root populations of a rhizobacterial strain of *Pseudomonas fluorescens*. If microbial numbers are to be expressed as colony forming units (CFU) per gram of rhizosphere soil, a subsample of the rhizosphere soil should be weighed, oven-dried, and weighed again to determine soil moisture content. For phyllosphere samples there are fewer difficulties, as generally the phyllosphere will be more or less synonymous with the phylloplane (plant surface).

A variety of methods have been used to separate rhizosphere microbes from root surfaces, and phyllosphere microbes from leaf surfaces. These methods include washing techniques (in flasks or tubes on a platform or wrist action shaker), vortexing (with or without additional agitation, for example with added glass beads), sonication, and blending or maceration. The method used for removal of microbes from either the rhizosphere or the phyllosphere affects the recovery of populations (Donegan et al. 1991; Kloepper et al. 1991). Washing or homogenizing diluents commonly include sterile tap or distilled water, saline solution, or buffer solutions. Regardless of the method, consideration must

be taken of whether rhizosphere or phyllosphere microbes might be killed by the process, resulting in artificially low counts, and/or whether growth in the diluent may occur, possibly resulting in inflated counts. Freezing leaf samples for more than 3 days prior to processing is not recommended as recovery of bacteria has been shown to be adversely affected (Donegan et al. 1991).

The dilution plate count is one of the most widely used methods for enumeration of microbes. However, it is well established that because indirect counts take into account only culturable microbes, they generally underestimate actual microbial populations. Typically, only a small fraction (0.01–10 percent) of the number of cells observable by direct microscopy is recovered by the plate-count procedure. Skinner et al. (1952) listed several reasons for inadequacies of the plate count procedure for bacterial isolation; these include (1) clumps of bacterial cells may give rise to single colonies on a plate; (2) antibiosis and competition on plates cause some colonies to fail to develop; and (3) even so-called 'general' growth media are usually selective in some respect. Many cells that are metabolically active do not produce colonies on solid media. Plate counts estimate only those cells that are tolerant of the medium and incubation conditions to which they are subjected (Zuberer 1994). In contrast, the plate-count procedure may provide an apparent overestimation of fungal or actinomycete biomass if clusters of spores are present, since each spore may give rise to a colony on the plate. To accommodate the enormous size of most microbial populations in environmental samples, as well as the microscopic size of individuals, the main principle of enumeration is dilution of the population to countable numbers. Usually, an investigator will add components to the isolation medium which inhibit either fungi or bacteria.

From leaf or root surfaces, it is possible to directly isolate fungal and bacterial propagules by pressing the surface of the leaf or root segment on to an agar surface, then removing it. This method has the advantage of providing some information about the microbial spatial distribution on the leaf surface. It is also possible to pour a small volume of molten agar on to the leaf surface, allow it to solidify, and then to transfer it to fresh medium (Langvad 1980). Testing surfaces for fungal spores is done similarly, but with single-sided tape, and the spores are then identified microscopically (Knudsen and Hudler 1987). Additional information on sampling, including preparation of serial dilutions and plating techniques, is provided in Dandurand and Knudsen (2001) and Zuberer (1994).

QUANTIFYING PROKARYOTE METABOLIC ACTIVITY IN SOILS

Determining the metabolic status of microbial cells in natural habitats is significant, because metabolic status largely determines the effects that the microbes have on their environment. In contrast, determining the identity and distribution of microorganisms can only provide information on their potential environmental activity. Historically, a great deal of research in soil and plant microbiology has focused on biochemical processes, including microbial roles in the processes of biogeochemical cycles, but necessarily many studies were performed in vitro or by using artificially constructed systems. Frequently, the potential metabolic capabilities of microbial populations in natural systems have had to be extrapolated from capabilities observed in the laboratory setting.

Traditional methods, with respirometry being the most notable example, have provided a wealth of information on total microbial metabolic activity in soils but have not always provided a deeper understanding of soil microbial community structure and function. It has long been known that the majority of soil microbes are not amenable to recovery by standard cultural techniques, and often the environmental role of these organisms, if they were detected at all, could only be guessed at. However, recent advances in molecular biology, fluorescent stain technology, and microscopy have provided new and/or improved tools to detect and characterize soil microbes in situ, including their abundance, genetic makeup, and environmental activities. Particularly exciting advances have been made in our ability to observe, under natural conditions and with minimum perturbation, many aspects of microbial physiology that previously could only be demonstrated with pure cultures under highly controlled conditions. Also, by helping to escape the limitations of pure culture methods, these new techniques have provided insight into the roles that individual microbial populations play as contributing members of microbial consortia.

Microbial metabolism can be defined as the sum total of all the chemical reactions that occur in microbial cells, and the seemingly infinite variety of metabolic processes and products suggests potential for a correspondingly vast array of detection methodologies. The scope of available technology for monitoring microbial metabolic activity is increasing so rapidly that it is difficult to catalog the available methods. However, methods can be broadly categorized as those that detect end products or intermediate products of catabolic or anabolic activity (e.g. detection of carbon dioxide produced by aerobic respiration, via respirometry), those that attempt to correlate fluxes in specific structural components of the microbial biomass (e.g. phospholipid ester-linked fatty acids) with metabolic activity levels, and those that are designed to detect the biochemical indicators of metabolism (e.g. RNA, specific enzymes) or the specific products of gene expression.

Soil, the rhizosphere, and the phyllosphere are populated by complex communities of organisms, including microbes (bacteria, Archaea, fungi, Protists) but also typically including plant and animal components. The

rhizosphere and phyllosphere are defined by the presence of a plant, so it is inherently impossible to characterize microbial activity in these habitats through the study of genetically uniform microbial strains in isolation. Determining microbial contributions to these communities may require a variety of techniques with different areas of focus. For example, it has long been known that microbes may be metabolically active even though they are not culturable. Furthermore, quantification of the viable microbial biomass may help elucidate the potential for specific microbial metabolic activities in a particular habitat, but the nonviable biomass may also be important as a component of the food web, despite its lack of a direct metabolic contribution. Although it is possible and common to make inferences about microbial biomass based on microbial community metabolic activity, it is important to note that these may not be strongly correlated; i.e. high metabolic activity does not necessarily mean an actively growing, dividing microbial community. Also, it is important to remember that microbial physiological activities are often strongly affected by the physical arrangement of the members of a population, especially aggregations such as those that occur in biofilms, on root surfaces (Dandurand et al. 1995, 1997), and in soil microsites. Physiological and spatial heterogeneity have important implications for the ecology of microbial populations and communities, and the ability of recently developed molecular and microscopic methods to address heterogeneity in environmental samples is especially exciting. Below, several of the most popular methodologies for quantifying microbial metabolic activity are briefly discussed. In each case, references are provided to original reports and more extensive, step-by-step protocols. The related subject area of bioreporter gene technology, which allows the analysis of in situ gene expression by supplying assayable gene products, and in which the gene product of interest is difficult or impossible to assay, is briefly discussed below. Similarly, biosensor technology is very promising for environmental microbiology; recent reviews on applications of biosensors for environmental microbiology are available (Burlage 1997).

Several methods for estimating metabolic activity levels of microbial populations involve quantifying cellular pools of specific biochemical components, including RNA, DNA, ATP, and total adenine nucleotide (TAN). Because the specific growth rate of bacteria is dependent on cellular amounts and synthesis rates of ribosomal RNA (rRNA), there is a strong correlation between cellular RNA content, or RND:DNA ratio, and growth rate (Kemp et al. 1993). ATP and TAN pool turnover rates can provide estimates of energy flux and specific growth rate in natural microbial populations. Kemp et al. (1993) described procedures to measure cell-specific quantities of rRNA and DNA in order to quantify the frequency distribution of activity among cells. In this procedure, fluorescently labeled oligonucleotide probes are hybridized to complementary 16S rRNA sequences in intact cells. Cell fluorescence, which is proportional to cellular rRNA content, is then measured, and compared with measurements of DNA content obtained by fluorescence of 4′, 6′-diamino-2-phenylindole hydrochloride (DAPI)-stained cells, generating a rRNA:DNA ratio for individual cells. Procedures for measuring rates of stable RNA synthesis have been applied to bacterial cultures as well as aquatic bacteria, based on the uptake and incorporation of radiolabelled adenine into cellular RNA (Karl 1979). Methods for simultaneous quantification of RNA and DNA synthesis rates also have been developed and used for estimating rates of growth, cell division, and biomass in microbial communities (Karl 1981, 1993). Recently, Lee et al. (1999) used a combination of fluorescent in situ hybridization (FISH) performed with rRNA-targeted oligonucleotide probes and microautoradiography, to quantify specific substrate-uptake profiles of individual bacterial cells within microbial communities.

Genetic methods

Recent advances in molecular biology have made it easier to analyze the genomes and quantify the genetic diversity of soil- and plant-associated microbes, as well as to track them in the environment (Bramwell et al. 1995; Louws et al. 1999). Much of this research has been motivated by the need for rapid and accurate detection of plant and animal pathogens, but the methods are applicable to many different aspects of environmental microbiology. Some of the DNA-based microbial characterization methods are dependent on PCR amplification, while others are not. Examples of the latter include DNA–DNA reassociation kinetics, characterization of plasmid profiles, and restriction enzyme analysis of total genomic or plasmid DNA. PCR-based approaches are often more useful because they require smaller amounts of DNA; also, they tend to be faster, more sensitive, and more specific. The main methods for analyzing and quantifying microbial genomes by PCR-based methodology include: repetitive DNA PCR (rep-PCR), rDNA-based PCR, amplified fragment length polymorphism (AFLP) analysis, and arbitrarily primed PCR (AP-PCR) randomly amplified polymorphic DNA (RAPD) (Louws et al. 1999).

A number of technical difficulties are associated with extraction and analysis of nucleic acids from soil; for example, DNA may be tightly bound to humic materials and clays. A number of protocols have been published for direct extraction of nucleic acids from soil, and the technology is rapidly evolving in this area (Levin et al. 1992; Pepper and Dowd 2002). Because PCR-based protocols are so highly sensitive, certain problems may arise. For example, only a very small quantity (e.g. a few molecules) of PCR-generated fragments can be

sufficient to cross-contaminate samples of subsequent PCR runs, resulting in the detection of false positives. A number of recommendations have been suggested to avoid such contamination (Carrino and Lee 1995; Kwok 1990). Because PCR can amplify DNA from dead cells as well as live ones, it may produce false positives. Additionally, PCR cannot directly distinguish viable but not culturable (VBNC) cells from culturable cells. One approach, BIO-PCR, was developed to circumvent this problem when assaying for plant pathogenic bacteria; with BIO-PCR, samples are first plated on to growth medium to culture any viable cells, before PCR analysis (Schaad et al. 1995). This approach has been used successfully for bacteria in soil as well as for plant- and seed-associated bacteria. When PCR is used to detect plant-associated microbes, there is the possibility of the presence of sample-related compounds that can inhibit the polymerase reaction. Wilson (1997) reviewed methods to avoid potential problems with inhibitory compounds.

Use of marker and reporter genes

Recently, genetic engineering of biocontrol agents with reporter or marker genes has provided useful tools for detection and monitoring of introduced biocontrol agents in natural environments (Green and Jensen 1995; Lo et al. 1998; Bae and Knudsen 2000). For example, the selectable hygromycin B phosphotransferase (*hygB*) gene, coding for resistance to this antibiotic, has been used to detect fungal biocontrol agents in the rhizosphere and phyllosphere (Lo et al. 1998). The β-glucuronidase (GUS) marker gene is also a promising tool for ecological studies of biocontrol agents, because of the low background activity of GUS in fungi and plants, the relative ease and sensitivity of detection (Roberts et al. 1989), and the apparent lack of influence of GUS expression on biocontrol efficacy. However, some background GUS activity may be present in unsterile systems or natural soils. The green fluorescent protein (GFP) of the jellyfish *Aequorea victoria* has also been developed as a reporter for gene expression (Chalfie et al. 1994). It has been successfully cloned and expressed in a variety of different organisms including plants, animals, fungi, and bacteria. GFP requires only ultraviolet (UV) or blue light and oxygen to induce green-fluorescence. An exogenous substrate, such as GUS requires, is not needed for the detection of GFP, thus avoiding problems related to cell permeability and substrate uptake.

Advances in microscopy

A number of methods to quantify metabolic activity and/or biomass of individual microbes, populations, or microbial communities involve direct microscopic observation of cells. These include simple measurement of cell size and size distributions, formation of microscopically observable metabolic products, fluorochromes used as 'physiological stains,' and genetically based marker and reporter systems. Techniques used to investigate root biofilm communities have included confocal microscopy with or without targeted rDNA probing, electron microscopy (SEM and TEM), and PCR-assisted rDNA RFLP/sequence analyses. Most of the wide range of potential microscopic techniques have been attempted for visualization of microbes on root and foliar surfaces, including bright-field, phase-contrast, and differential interference, epifluorescence, scanning and transmission electron microscopy, and atomic-force microscopy. In general, direct visualization for quantitative purposes can be difficult because of opacity of the substrate and the small size of microorganisms; spatial associations are difficult to describe because of the short working distance and the high magnification needed to see them. Phase-contrast or interference microscopy of fresh material is possible, but associated soil and root material can give confusing background for observation of microorganisms. Fluorochromes and other stains are commonly used to observe microbes on plant surfaces. However, autofluorescence of plant tissue can be a problem when using fluorochromes to detect microbes on plant surfaces.

Sampling considerations

A number of special considerations arise when sampling microbes from the rhizosphere and phyllosphere. Parberry et al. (1981), Hirano and Upper (1983, 1986), Kinkel et al. (1995), and Kloepper and Beauchamp (1992) have reviewed some of the difficulties inherent in sampling the phyllosphere and the rhizosphere. Problems include the non-normal distribution of microorganisms, selection of sampling strategy, scale of sample, and sample unit. The choice of sampling strategy, scale of sample, and sample unit can all have a significant effect on the results of an experiment. The type of sampling strategy used in sampling the rhizosphere and the phyllosphere is often dependent on the question that is being asked. It is generally recommended that samples be taken at random so that the assumption of independence of samples for standard statistical tests (e.g. analysis of variance) is met. However, sampling of microbes from the rhizosphere, in many cases, cannot be done randomly. For example, colonization is often determined by taking root segments at a prespecified distance (e.g. 1-cm segments 2 cm below the soil line). Another example, which can result in autocorrelated data, is when roots are sequentially sampled in order to assess the root-colonizing ability of a microbe. In these situations, one must verify that the data meet the assumption of the statistical analysis prior to conducting the tests.

The selection of sample scale and sample unit is based on biological features of plants, reduction of sample variance, ease of processing, and other methodological constraints. When epiphytic bacterial populations were sampled, a high level of variability was reported among sample units at every scale investigated (leaf segments, leaflets, or whole leaves) (Kinkel et al. 1995). In contrast, variability of rhizobacteria was significantly less when whole roots were sampled compared with root segments (Kloepper et al. 1991). Thus, for phyllosphere sampling, Kinkel et al. (1995) suggested that selection of sample scale and unit should not be based only on the assumption that the variance is scale dependent but may be more appropriately based on methodological and biological considerations. Although sample variance may be reduced when sampling whole-root systems rather than root segments, this sample scale may not always be feasible (e.g. when sampling mature plants).

Natural populations and habitats are spatially heterogeneous, i.e. organisms and their resources are usually not uniformly distributed over space or time but are found in different degrees of aggregation. Several theoretical studies have demonstrated the importance of spatial heterogeneity for population and metapopulation persistence and abundance (Hanski 1991). Hirano and Upper (1993) demonstrated changes in frequency distributions of epiphytic bacterial populations on populations of habitats (individual leaflets) within a plant canopy. However, despite continuing demonstration of the theoretical and practical importance of spatial processes to ecology, relatively few mechanistic studies of the factors that create heterogeneous spatial distributions and the processes by which they occur in nature are available. As pointed out by Hirano and Upper (1993), an understanding of factors that regulate epiphytic bacterial population dynamics must address mechanisms that underlie variability.

Most natural environments are spatially structured by various energy inputs that result in patchy structures or gradients (Legendre and Fortin 1989). Thus, biological organisms are rarely distributed in a random or uniform manner. The rhizosphere is a good example of this, since energy input is largely due to root deposition. Spatial variability of nutrient deposition from seeds, as well as the spatial presence of roots, may influence sites of colonization by rhizosphere microbes and the quantity and composition of root deposition varies along the root. Sites may be preferentially colonized by some microbes, such as bacteria in cell junctions (Rovira 1956) or zoospore encystment in the zone of root-cell elongation (Hickman and Ho 1966; Mitchell and Deacon 1986; Zentmeyer 1961). Although the tendency for both phyllosphere and rhizosphere microbial populations to conform to lognormal or similar frequency distributions has been noted (Hirano et al. 1982; Loper et al. 1984; Newman and Bowen 1974), the actual spatial variability of these populations is less well documented. Appropriate characterization of the spatial variability inherent in soil- and plant-associated microbial communities will allow us to improve quantification of the organisms and processes under study.

Natural waters	3	Bacteriological analysis	10
Pathogenic bacteria in aquatic environments	7	Principles of pathogen detection	15
Natural self-purification factors	9	Strategies for rapid methods	15
		References	15

Bacteriology of water continues to be an important component in defining the quality of public health. In recent years, expanding methodology has led to the discovery of additional pathogens as the cause of waterborne outbreaks. As a consequence of these new discoveries, the focus on water quality is being redirected towards better characterization of the microbial risks associated with this vital resource. It is important to note that although water is essential to sustain life, it can be a hostile environment to humans when grossly polluted.

CHARACTERIZING THE BACTERIAL FLORA IN THE AQUATIC ENVIRONMENT

The bacterial flora of water is a composite of organisms indigenous to high-quality water or pristine waters plus all of the contributions from life's many controlled and uncontrolled uses or consumption of water.

Indigenous bacteria

These are naturally occurring bacteria found in waters that are remote from the activities of modern civilization. They are largely saprophytic organisms, some of which belong to the genera *Micrococcus*, *Pseudomonas*, *Serratia*, *Flavobacterium*, *Chromobacterium*, *Acinetobacter*, and *Alcaligenes*. There are indigenous bacteria that are difficult to detect in routine laboratory techniques because of their slow growth or fastidiousness. In the past, these organisms received little attention, but this attitude is changing because of problems with biofilm development in streams, ground-water extraction, water pipe networks, and industrial processes. An additional threat is that some opportunistic pathogens, such as *Legionella*, may be ubiquitous in the water environment.

Contributed bacteria

Rainfall runoff is a major contributor to changes in the bacterial flora found in water. Whereas rain or snow falling over the watershed contains only occasional bacteria acquired from air-borne particles (Table 1), the microbial and chemical qualities of rainwater drastically degrade upon contact with the soil (Geldreich et al. 1968). Various soil and fecal organisms are immediately accumulated into the drainage and merge as the bacterial flora. These organisms, though not normal inhabitants of high-quality water, either adapt to the aquatic environment or die out over time because of various environmental adversities. Predominant among these soil and vegetation organisms are the aerobic spore-forming bacilli, such as *Bacillus subtilis*, *Bacillus megaterium*, and *Bacillus mycoides*. Others, such as *Klebsiella pneumoniae*, *Enterobacter aerogenes*, and *Enterobacter cloacae*, may be found growing in the water- and food-conducting tissue of trees (Knittel et al. 1977), on crops, and on other vegetation. By use of special media, a variety of other specialized bacterial groups can be isolated. In the bottom sediments of

Data from Geldreich et al. 1968.

streams and lakes where oxygen is restricted, nitrate, sulfate-reducing, and methanogenic bacteria can be detected and impart disagreeable earthy odors and tastes during summer periods of low stream flow.

The microbial flora of sewage is predominantly from fecal wastes including pathogens shed from individuals in the community. These would include species of *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Leptospira*, *Streptococcus*, *Clostridium*, and *Vibrio cholerae* and pathogenic types of *Escherichia coli*. Other significant contributors to the flora of municipal sewage are introduced in combining stormwater runoff, laundry wash water, automatic car-washing water drainage, processing food wastes, and industrial discharges.

Within the complex flora of sewage-treatment sludge are organisms that are responsible for much of the biological breakdown of degradable waste products. Some of these beneficial organisms include the filamentous bacteria *Sphaerotilus natans*, *Haliscomenobacter hydrossis*, *Nostocoida limicola*, *Microthrix parvicella*, *Flexibacter*, *Microscilla*, and *Nocardia* (Eikelboom 1975) and the important floc-forming bacteria (*Zoogloea ramigera*), along with *Proteus* and the anaerobe *Clostridium sporogenes*.

Animal feedlot operations that require the confinement of cattle in small areas create a fecal-waste-removal problem equal to the domestic waste discharges of small cities (Geldreich 1972b). If the animal waste is not discharged to a lagoon or landfill, stormwater runoff over the animal feedlots will bring massive loads of fecal pollution to the drainage basin. While cattle feedlot wastes may be a major source of bacterial pathogens (particularly, *E. coli* O157:H7), poultry-farm fecal wastes can contribute a variety of salmonellae into the drainage basin that could also be a resource for water supply downstream.

Food processing, beet-sugar extraction, and cane-sugar production have a drastic impact on the bacterial flora and the self-purification capacity of receiving waters. Elevated concentrations of nutrient wastes lead to oxygen depletion of the receiving waters plus an increase in environmental coliforms and fecal streptococci, particularly streptococci variants on biotypes (Mundt 1963; Mundt et al. 1966b). Most troubling is the extended persistence of *Salmonella* spp. under these conditions (Geldreich 1972a).

Discharges of poorly treated paper-mill waste to receiving streams or lakes can also have a severe impact on the microbial quality of surface waters. The association of environmental *Klebsiella* with paper manufacturing and the excessive nutrients in paper-mill waste cause a tremendous regrowth of this coliform in downstream waters. Environmental *Klebsiella* spp. colonize plants at flower pollination. As the seed germinates, *Klebsiella* spp. establish a coexistence within the plant by metabolizing nutrients from wood sugars (cyclitols) in the nutrient- and water-conducting tissues during the life of the tree (Seidler et al. 1977). Another byproduct of paper processing is wastewater sulfites, which encourage the growth of biofilm mats of the nuisance organism

Table 2 *Microbial characterization of solid wastes from various cities*

Waste collection site[a]	Number of samples	Organisms per g wet wt[b]			
		Total viable bacteria[c]	Spores	Total coliforms	Fecal coliforms

b) Average moisture content was 41 percent.
c) Spread plates (trypticase soy agar + blood) at 35°C for 48 h.

Sphaerotilus natans along the shoreline of receiving streams.

Solid waste, generally referred to as garbage or rubbish, contains a multitude of items such as food discards, garden rubbish, manufactured products (paper, plastic, rubber, leather, textile, wool, metals, glass, ceramics), rock, dirt and ash residues, and also fecal material (Table 2). Much of the fecal material in urban areas is derived from disposable diapers, pet-litter material, and feces of rodents foraging for food in these waste collections (Geldreich 1978). Therefore, it is not surprising that solid wastes contain a large and varied microbial population that includes a wide spectrum of bacteria (aerobes, anaerobes, thermophiles), actinomycetes, and fungi (Cook et al. 1967). If properly disposed of through sanitary landfills, many of the problems (foraging wildlife, odors, unsightliness) common to open dumping are avoided. However, poor placement of landfill sites may result in the migration of leachates into nearby surface waters and groundwater resources.

NATURAL WATERS

Natural waters occur either at or near the surface of the earth. Surface waters are frequently exposed to contamination from soil, stormwater runoff, domestic sewage, agricultural and industrial wastes, and decomposing vegetation. On the other hand, ground waters can be expected to be of excellent bacteriological quality due to the beneficial percolation into underground strata (aquifers). During downward passage to an aquifer, perhaps several hundred meters below the surface, most of the surface contaminants are entrapped in the soil or porous rock layers. One exception is a rock stratum composed of limestone, which is very porous and often results in sink holes and caverns through which surface water passes without effective entrapment of contaminants. In other situations, excessive application of minimally treated wastewaters to land surfaces may overwhelm the natural soil barrier (Kowal 1982). Once the aquifer becomes contaminated, restoration of water purity is very slow, even with accelerated intervention such as pumping the water to a treatment site and then returning it to the aquifer.

Surface waters

Natural water resources are replenished through rain, snow, and hail. This atmospheric moisture comes in contact with particles of suspended dust and smog that immediately contaminate the rain as it falls to the earth. The more dust encountered, the greater is the bacterial contamination. In remote areas away from the plumes of air pollutants, the total number of organisms may not exceed 10–20/l. Springtime dust storms originating in large farming areas may mix with atmospheric vapor to transport one to two total coliforms per liter of rain over great distances. Snow tends to be less pure than rain, probably because the snowflakes have greater surface area on which to collect suspended particles in the atmosphere, and also because their low temperature is conducive to the survival of bacteria. However, in snow on the tops of remote mountains, where the air is clean, very few organisms are present. Apparently hail contains more bacteria than either rain or snow. Hail examined from a storm over Padua during July 1901 was found to contain 140 000 microorganisms belonging to nine different types (Belli 1902). This surprising finding was probably caused by air currents that cycle the raindrops through periods of freezing and thawing as they repeatedly traverse plumes of dust in the air before falling to the ground. The number of organisms in ice depends on the nature of the water from which the ice was formed. With the exception of ice from glaciers, it is generally impure. Various heterotrophic bacteria, including coliforms and pathogens, have been found in ice made with contaminated water.

In remote areas, where human and farm animal populations are sparse, most organisms in water originate from soil with little evidence of contamination except

Table 3 *Indicator correlations with* Salmonella *occurrences in ambient waters (densities per 100 ml)*

Salmonella (%)	Clostridium[a]	Fecal streptococcus[a]	Fecal coliform[a]	Total coliform[a]
0	0	0	0	0

66	200	1 500	5 000	50 000
99	250	3 000	10 000	100 000
100	2 500	30 000	100 000	1 million
100	6 250	250 000	850 000	2.5 million

Data modified from Nemedi et al. (1984).
a) Densities per 100 ml.

for a few fecal coliforms (<100 organisms per 100 ml) originating from occasional wildlife inhabiting the immediate vicinity. Beaver and muskrats on the river banks, and significant concentrations of deer, elk, and other game animals in grazing plains and forest reserves, are responsible for a residual level of fecal microorganisms in water.

As these waters travel down a watershed, contact with agricultural and industrial activities increases and the river becomes laden with a variety of domestic and industrial wastes. As a consequence, rivers in most countries are heavily contaminated. Some measure of the potential occurrence of salmonellae in Hungarian ambient waters grouped at various average densities for several indicator groups is presented in Table 3. These data support the position that the greater the magnitude of fecal pollution, the greater the chance that some bacterial pathogens may also be present. Absence of any detectable fecal coliforms does not mean that there is no risk from *Giardia*, *Cryptosporidium*, or a virus. These pathogenic agents frequently occur in small densities requiring the testing of larger-volume (>10 liter) samples. For this reason, a surrogate indicator examination at only one sample volume of 100 ml is not going to provide sufficient precision to ascertain the potential for extremely low-density pathogen occurrences.

In a study of surface-water supplies used by 20 cities in the USA serving a total population of seven million people, it was estimated that the minimum wastewater component of the raw source water ranged from 2.3 to 16 percent and increased to predominantly wastewater for several cities during low-flow periods (Swayne et al. 1980). This public-health risk was verified by the finding of various serotypes of *Salmonella* at each water-plant intake. Bacteriological examination of raw water quality at the water treatment plant intakes of Omaha, Nebraska, St Joseph, Missouri, and Kansas City, Missouri, on the Mississippi River (Table 4) frequently revealed fecal coliform densities in excess of 2 000 organisms per 100 ml (Report 1971). This fecal pollution load resulted from inputs of raw sewage, effluents from primary and secondary wastewater treatment plants of differing efficiencies, cattle feedlot runoff, and discharges from meat- and poultry-processing plants. Fecal discharges entrapped on soil also entered the drainage basin by the flushing action of storm events. The major raw-water quality concern is that human pathogens may also be present in surface waters used for water-supply sources or body-contact recreational pursuits.

Similarly high-elevation lakes in remote parts of a watershed will contain high-quality water (unless inhabited by flocks of aquatic birds), whereas those in the lower part of the watershed are fed with surface drainage from metropolitan areas and intense agricultural activity. For large lakes such as the North American Great Lakes, long retention time and vast volumes of water serve to buffer these magnificent water resources from the impact of stormwater runoff. Unfortunately, pollution plumes around waste-water discharges may spread to new areas by wind-driven currents. At greatest risk are the many small lakes surrounded by residential development that ultimately become polluted from sporadic drainage of septic systems and runoff from neighborhood lawns.

Ground waters

Groundwater resources are the major source of water supply for many communities, farms, and individual families world wide. In rural areas, many water supplies consist of dug wells less than 10 m deep. In these wells, source water is influenced by surface-water runoff that percolates through the soil. Since there is no protective bedrock perched on top to seal off surface contaminants, water quality is erratic. Many private wells are in this category, causing the untreated water supply to be an unsafe source of drinking water. Bore holes are often of better quality because casings are driven to depths of at least 30 m and soil depth does provide a barrier to much of the surface contamination. In general, public water supplies that use ground water attempt to reach high-

a) Geometric mean.

yield aquifers at greater depths, often 300 m or more, to satisfy a greater water demand and reliable source of bacteriologically safe drinking water.

The quality of water flowing from springs depends mainly on their source and surroundings. Unfortunately, in many instances the source is unknown and could be under the influence of surface water, so quality may vary as a result of rainfall events and other activities on the watershed.

Cisterns

This source of water is generally rainfall from some catchment surface, which often is a residential roof or paved hillside for water to drain down into a storage tank. Bacteriological quality is a reflection not only of rainwater and dust particles but also of fecal contamination from birds perched on the catchment surface. Table 5 illustrates the varying densities of several bacterial indicator groups, the standard plate count, and *Pseudomonas aeruginosa* that may be encountered in tropical cistern waters. In some areas of the world, cisterns have become a blend of rainwater augmented by purchased water during the dry season.

Swimming pools and therapeutic baths

Swimming pools most often use treated municipal supplies for filling, but the water may also be derived from thermal springs, mineral springs, or the ocean. Pool operation and construction materials (cement, plastic, and redwood) have a definite effect on microbial growth (Castle 1985; Davis 1985) as does variability in water temperature in both indoor and outdoor pools (Schiemann 1985). Outdoor pools can be contaminated through stormwater drainage, soil, vegetation debris, and pets and wildlife. Microorganisms of major concern are those from the bather's body and mucosa and include those causing infections of the ear, eyes, upper respiratory tract, skin, and intestinal tract (Favero and Drake 1966). Obviously the number of bathers is another serious contributor to the deterioration of water quality. Major microbial contributions are from saliva and sinus drainage, as well as fecal contamination from the defecation of infant bathers. Pool-water disinfection can suppress many microorganisms, but effectiveness is limited by short contact time, disinfectant demand created by bather body oils, particulates, and sunlight exposure.

Bottled water

This water is generally an acceptable alternative drinking water supply and the primary alternative for emergency use (public supply contamination, foreign travel in developing nations), recreational/sports, and use in reconstituting baby formulae. Bottled water

sources are most often ground water or springs, but in recent years reprocessed public water supply (distilled, carbon-filtered, deionized, ultraviolet-radiated, or reverse osmosis desalinated) has also become available. Quality of the source water is dependent upon watershed protection, limited access to the area of extraction, and protected housing around well heads and spring outflows. Bottling operations follow prescribed sanitary codes for dispensing a food product and disposable plastic containers are commonly used to avoid possible contamination introduced from returnable glass bottles. As might be anticipated, microbial quality of freshly bottled water (within 48 h of bottling) is usually excellent. The rate of microbial change is related to a variety of factors including assimilable organic nutrients in the water, organisms competing for dominance in the microbial flora, water pH, and storage temperature. High-quality bottled waters undergo a slow rate of change because growth of the indigenous organisms may take hours, not minutes, and the available nutrients are in trace amounts. Waters bottled from sources that have fluctuating microbial populations that exceed 1 000 organisms per milliliter may contain coliforms and some opportunistic pathogens. Such bottled waters are of concern because the higher densities of heterotrophic bacteria may mask the laboratory's ability to detect fecal pollution and pathogens that might be present. Table 6 illustrates the variability in bacterial density and frequency of coliform-positive samples among bottled waters of unknown age purchased from retail outlets.

Although reported disease outbreaks due to contaminated bottled water are rare, the lack of documentation does not lessen the concern posed by use of this alternative. Any contaminated bottled water supply presents a unique hazard because of the widespread distribution of the product, which is not necessarily confined to a single community. In April to November 1974, Portugal had a cholera epidemic that caused 2 467 confirmed cases and 48 deaths (Blake et al. 1977). Most of the country was affected and the source of the infections was traced to the consumption of a brand of commercially bottled water as well as to poorly cooked shellfish. The source water may have become contaminated from cholera-infected individuals living on the watershed or involved in the bottling operation. This outbreak clearly illustrates the importance of watershed protection for ground waters and springs plus the need for effective sanitation practices during bottling operations.

Estuarine areas

These are the areas where fresh water mixes with the salt water environment either through direct discharge to the sea or by tidal flooding of freshwater pools near the ocean. Water-quality protection and enhancement of estuarine waters are particularly important for shellfish cultivation. Release of wastes to shellfish-growing waters brings a variety of organisms to the water, some of which may remain in suspension for varying periods before becoming entrapped in water turbidity. Most of the organisms reaching the area are either in aggregates or adsorbed to fecal cell debris and quickly accumulate in the bottom sediments, aided by the settling action of recirculating bottom silts. This natural deposition process concentrates much of the contaminants at the water–sediment interface, where hard- and soft-shell clams browse for food. For these reasons, it is essential that shellfish-harvesting areas be given a degree of protection from pollution that almost parallels the requirements for drinking water supplies. A zero tolerance for fecal pollution is not achievable in most shellfish-growing waters, so there needs to be a maximum permissible contaminant level recognized for authorized harvesting to minimize the public-health risks from consumption of raw shellfish.

Table 6 *Comparison of standard plate-count variability among brands of bottled water*

Brand	Sample type[a]	No. of samples	Count range[b] (SPC/ml)	Coliform positive samples[c]

c) One or more coliforms per 100 ml.
d) Imported bottled water, carbonated.

Coastal waters

Coastal marine waters deservedly receive much attention because of their use as recreational bathing waters and fishery resources. Major sources of pollution are stormwater runoff along the beach areas, offshore dispersion of sewage through outfalls, sanitary wastes from ships in harbor, oil spills, and disposal of municipal garbage outside designated ocean dumping areas. In the sea, off heavily polluted bathing beaches, the coliform content may rise to 200 000 or more per 100 ml and salmonellae are frequently present (Report 1959). Organic enrichment of the sea by pollution enhances the activities of sulfate-reducing bacteria in sediments near the water interface and methanogenesis in the sediments below. After discharge from a sewage outfall, fecal and enteric bacteria rapidly disperse if there is good diffuser design and high tidal energy. At Sidmouth, Devon, which has an outfall discharging 460 m from the high-water mark, the median coliform count at the shore near the outfall was 73 organisms per 100 ml in 1965, equivalent to dilution of the sewage by a factor of 400 000 (Gameson et al. 1967).

PATHOGENIC BACTERIA IN AQUATIC ENVIRONMENTS

Numerous pathogenic agents have been isolated from ambient waters used for water supply, recreational bathing, and irrigation of garden salad crops (Geldreich and Bordner 1971; Geldreich 1972a; Rosenberg et al. 1976; Cordano and Vergilio 1990; Rose 1990). The list of water-borne pathogens in polluted temperate and tropical drinking waters (Table 7) includes many of the same bacterial and viral agents but differs by the additional hazards of a variety of water-borne parasites with alternating life cycles between man and aquatic life forms. The list of water-borne agents will increase as new methodologies evolve to detect the more elusive organisms that cause gastroenteritis or other human illnesses.

The magnitude of pathogen reservoirs in the environment is exacerbated by expanding human populations worldwide. Population crowding and the unregulated development of satellite communities place undue pressures on sanitation infrastructural barriers (sewage collection and treatment, solid waste disposal, potable

water supply processing and its distribution). Add to these problems the mobility of people throughout the world and it becomes apparent that an outbreak can quickly spread by person-to-person contact and through secondary water contamination, reaching epidemic proportions.

Pathogen pathways

Although sewage collection systems have decreased public-health risk in urban centers, this practice only serves to transport the collected wastes to some selected destination, hopefully where treatment is applied prior to release into a watercourse. Raw sewage discharges to receiving waters have often been shown to contain a variety of pathogens. The density and variety of human pathogens released are related to the population served by the sewage-collection system, seasonal patterns for certain diseases, and the extent of community infections at a given time. Some indication of the relative occurrences of various pathogens in raw sewage is given in Table 8 for two cities in South Africa (Grabow and Nupen 1972).

In major river systems receiving discharges of meat-processing wastes, raw sewage, and effluents from ineffective sewage treatment plants, the densities of *Salmonella* spp. may be substantial. It has been calculated that the Rhine and Meuse rivers carry approximately 50 million and 7 million *Salmonella* bacilli per second, respectively (Kampelmacher and Van Noorle Jansen 1973). The Missouri River represents another example of a pollution conduit, transporting a fecal pollution load from raw sewage, effluents from primary and secondary treatment plants of differing efficiencies, runoff from numerous cattle feedlots, and waste discharges from meat- and poultry-processing plants. As a consequence, it is not surprising that various *Salmonella* serotypes and viruses have been detected at the public water supply treatment plant intakes (see Table 4, p. 215).

Cattle feedlots and poultry operations result in an intense concentration of farm animals and their fecal wastes in a confined space. In cattle feedlot operations, the density of beef cattle per square mile may approach 10 000 animals. Under such restrictions, removal of fecal wastes is a major disposal operation. The closeness of farm animals in confined feeding operations invites the spread of disease in a healthy herd or poultry flock. Some farm animal pathogens (*Salmonella*, *E. coli* O157:H7, *Giardia*, and *Cryptosporidium*) are also major human pathogens. Unless contour cultivation and stormwater retention ponds are undertaken to reduce runoff, fecal material transported in stormwater runoff from cattle feedlots and poultry farms becomes a major source of contamination in rural watersheds, polluting streams and lakes in its drainage path. Direct recycling of untreated farm animal wastes and sewage by application to fields as fertilizer can become a serious contributor of pathogens to salad crops and ground water.

Wildlife refuges may also be a significant source of fecal contamination, particularly on a seasonal basis, since many wild animals are migratory by instinct in their search for food. The largest reservoir of wildlife pathogens will be found in warm-blooded animals such as beaver, deer, coyote, ducks, and gulls that are permanent residents of watersheds (forests, prairies, lakes, reservoir impoundments). These animals and others serve as reservoirs for *Salmonella*, *Campylobacter*, *Yersinia*, *Giardia*, and *Cryptosporidium*. Wildlife is also attracted to protected watershed areas (forest reserves, private lands) where human activities over the watershed are more restricted (Walter and Bottman 1967). Protected near-shore water environments are often the location of large beaver colonies, including individual animals infected with *Giardia*. Infected coyotes, muskrats, and voles are other wild animals that may be involved in the shedding of *Giardia* cysts and other pathogens into the aquatic environment. Terrestrial birds and waterfowl can be sources of bacterial pathogens. Songbird populations include individuals that may be infected with *Salmonella*. Seagulls are scavengers that frequent open rubbish dumps, eat contaminated food wastes, and contribute *Salmonella* in their fecal droppings to coastal lakes (Alter 1954; Fennel et al. 1974). In one instance, seagulls were the contributors of *Salmonella* to an untreated surface supply in an Alaskan community, causing several cases of salmonellosis (Anonymous 1954). Pigeons colonizing two water storage towers in Gideon, Missouri, were considered the

Table 8 *Microbial densities in municipal raw sewage from two cities in South Africa*

Organism or microbial group	Average count per 100 ml

Source: Grabow and Nupen (1972).

source of *Salmonella typhimurium* that contaminated the water supply, causing 600 illnesses and four deaths (Clark et al. 1996). Wildlife is also believed to be the source of *Campylobacter* that contaminated streams and reservoirs of low turbidity in Vermont (Vogt et al. 1982) and British Columbia (Report 1981). Vacationers to national parks in Wyoming became ill after drinking water from mountain streams, resulting in a 25 percent increase in outbreaks state-wide involving *Campylobacter enteritis* (Taylor et al. 1983).

Pathogen persistence

Upon discharge into the aquatic environment, the persistence of pathogens becomes a variable determined by many factors. For example, *Salmonella* strains were detected with regularity in surface water up to 250 m downstream from a wastewater treatment plant, but never at sample sites 1.5–4 km upstream (Kampelmacher and Van Noorle Jansen 1976). Various *Salmonella* serotypes transported by stormwater through a residential storm sewer and a wash-water drain at the University of Wisconsin experiment farm were isolated with regularity at a swimming beach approximately 800 m downstream (Claudon et al. 1971). Salmonellae were also detected in coastal waters from several Staten Island beaches and from shellfish harvested in New York harbor (Brezenski and Russomanno 1969).

Excessive biochemical oxygen demand (BOD) or total organic carbon (TOC) in a poor-quality wastewater effluent combined with low stream temperatures can also affect pathogen persistence. For example, *Salmonella* were isolated in the Red River of the North (North Dakota, Minnesota), 35 km downstream of sewage discharges from Fargo, North Dakota, and Moorhead, Minnesota, during September (Report 1965; Spino 1966). By November, *Salmonella* strains were found 99 km downstream of these two sites. In January, with the beginning of the sugar-beet-processing season, wastes reaching the stream under cover of ice brought high levels of bacterial nutrients. *Salmonella* were then detected 117 km downstream – a flow time of 4 days from the nearest point-source discharges of warm-blooded animal pollution.

NATURAL SELF-PURIFICATION FACTORS

Natural waters provide a fragile purification buffer to limited amounts of raw wastes and stormwater runoff entering the drainage basin. Every stream, lake, estuary, and water aquifer has some limited capacity to self-purify; surface waters generally have greater capacity than ground waters. Stream self-purification is a complex and ill-defined process that involves bacterial adsorption with sedimentation, nutrients, predation, competitive microbial populations, dilution, aeration, water temperature, water pH, and solar radiation (Geldreich 1986).

Retention of surface water in lakes, impoundments, and streams is an important contribution to water-quality enhancement. Storage and sedimentation of surface water often improves the microbial quality. Many organisms are inactivated by natural self-purification processes, whereas others are removed from the water through natural siltation (Romaninko 1971; Dzyuban 1975; Geldreich et al. 1980). These water-quality improvements are variable and are directly proportional to retention time, dilution, and the number of contributing sources (Geldreich 1991). In temperate zones with pronounced seasonal temperature changes, many lakes and impoundments are subject to periods of thermal stratification in the summer and winter and destratification (water turnover) periods in spring and

autumn. During stratification, water movement in the deeper portion of raw-water reservoirs becomes restricted, generally creating a zone of maximum bacterial contamination in the water layer above the thermocline (Weiss and Oglesby 1960; Collins 1963; Niewolak 1974; Drury and Gearheart 1975). With destratification, water from the bottom and top layers mixes and develops a more uniform water quality. This mixing process causes decaying vegetation and entrapped organisms in settled particulates to re-enter the water column (Weiss and Oglesby 1960; Niewolak 1987). Heterotrophic bacterial populations (including coliform bacteria), turbidity, and humics from partially decomposed vegetation will temporarily increase in the water.

Fresh seawater brings about a fairly rapid decline in fecal bacteria, salmonellae, and viruses. The main inactivating agent is solar radiation at wavelengths less than 400 nm (Gameson and Saxon 1967; Gameson and Gould 1975; Chamberlin and Mitchell 1978; Fujioka et al. 1981). Tidal currents, sedimentation, and sunlight intensity are variable factors that dictate the effectiveness of solar radiation as a force in natural self-purification of coastal marine water contamination.

Biofilms in water

A biofilm is a colonization of various organisms in a slimy matrix of extracellular organic polymers (glycocalyx) at sites that offer surfaces for attachment and protection from the shearing action of water turbulence (Costerton et al. 1978; Characklis and Marshall 1990). Patches of biofilm may be found on submerged rocks in slow-moving streams, within water-supply and wastewater treatment basin structures and their connecting flumes, in the water-pipe environment of sediments and tubercles, and in water-supply-attachment devices used in hospitals and clinics.

The microbial community in a water pipe begins with pioneering organisms in the passing flow of water becoming lodged in sediment, pipe corrosion, and at water sumps created in the design of various water delivery devices (Geldreich and Reasoner 1989). Colonization follows once a critical mass of assimilable organic carbon complexes, nitrogen occurring compounds, and traces of phosphorus become absorbed in associated sediments and tubercles. This growth is further accelerated as water temperatures rise above 15°C (Geldreich and LeChevallier 1999). Over time the consortium grows in complexity, the more fastidious organisms with unique nutrient requirements (*Legionella*) being supported by metabolic byproducts released from other bacteria in the microbial community.

As a biofilm expands in a section of water-distribution pipe, fragments of this bacterial growth are dislodged under certain situations into the bulk movement of water supply: shearing action of water velocity; flow reversals; abrasive action of pipe-cleaning procedures on tubercles; or abrupt shifts in water pH that softens sediment deposits. Among the variety of bacteria sloughed off the pipe surface are coliforms bacteria, particularly *Klebsiella pneumoniae*, *K. oxytoca*, *Pantoea agglomerans* (*Enterobacter agglomerans*), *E. cloacae*, or *Citrobacter freundii*. Coliform releases in biofilm fragments may not be of public health significance per se but should not be ignored because of perpetual concern for a hidden fecal contaminating event (Percival et al. 2000). Biofilms also induce corrosion and increase disinfectant demands and customer complaints of taste and odors. Other bacteria of concern in biofilm include a variety of heterotrophic organisms (*Pseudomonas*, *Aeromonas*, *Flavobacterium*, *Proteus*, *Bacillus*, *Actinomycetes*, and fungi), some of which may be opportunistic pathogens causing nosocomial infections in the hospital environment (Costerton et al. 1981). The bacterial pathogen *Salmonella* has been demonstrated in laboratory research on biofilm development to have a very tenuous persistence because of competition from other organisms in the biological consortium (Camper et al. 1998).

WATER-QUALITY CRITERIA

Bacterial criteria for determining water quality have been directed primarily towards concern for microbial hazards to human health, although some thought has been given to health hazards to farm animals and aqua cultures of fish stocks, shellfish, and turtles (Report 1968, 1985). Indicators of fecal pollution have long been the predominant microbiological tool used to define the microbial quality of a water supply. However, there is growing evidence that water may transport not only intestinal pathogens via ingestion but also respiratory agents by inhalation and skin diseases through body contact. Thus, the microbial risks in water quality may require not only traditional criteria (heterotrophic bacteria, total coliforms, fecal coliforms, *E. coli*, fecal streptococcus, enterococcus) but also special surrogates such as *Clostridium*, aerobic spore formers, bacteriophages, and species-specific pathogens to evaluate health-risk status related to water use.

BACTERIOLOGICAL ANALYSIS

Standard methods for the analysis of a variety of waters are described in specific detail by the World Health Organization (Report 1984, 1992), the American Public Health Association (Report 1998), and the United Kingdom Report on Public Health and Medical Subjects (Report 1994), among other national documents worldwide. These methods relate to drinking water, recreational waters, swimming-pool waters, shellfish-growing

waters, wastewater discharges, recharge waters to aquifers, and other re-use applications.

For monitoring purposes, these indicators and various bacterial pathogens are detected by methods based on four principal procedures: pour or spread plates, selective cultivation in broth (multiple tube tests), membrane filter techniques, and enzyme–substrate reaction. More specific identification of selected heterotrophic organisms may be done by speciation of culture isolates.

Stressed organisms

Microbial detection must be based on methods that yield a high recovery of selected indicator groups or individual species. Recoveries are often 90 percent or better but are subject to some losses, which can be associated with injured bacteria in the water (McFeters et al. 1986; McFeters 1990). In various aquatic environments, competing organisms in the microbial community, toxic metal ions, toxic wastes, and inadequate disinfection are major causes of cell injuries. Many stressed organisms may thereupon become incapable of survival in standard laboratory procedures, a situation that can have a great impact on data interpretation. The public-health concern lies with bathing water, potable supplies, and shellfish beds that have indicator densities ranging below 200 organisms per 100 ml. It is important to note that while some enteropathogenic bacteria may also be susceptible to similar stresses, the potential for virulence remains and the injured cells recover after being injested by exposed indiciduals (LeChevallier et al., 1985; Singh et al. 1986; Singh et al., 1986).

Efforts to reverse these impacts on indicator organisms may include the use of a chelating agent and application of a dechlorinating compound in the sterile sample bottle, initially resuscitating the stressed cells by culturing in an enriched, nonselective medium with incubation for 2 h at room temperature prior to selective incubation on T7 agar at 35°C for the total coliform pupulation (LeChevallier et al. 1985). For recovery of injured fecal coliform cells, a two-layered agar using an overlay of tryptic soy agar on M-FC medium with incubation at 44.5°C provides a gradual sift to more selective nutrients (Rose et al. 1975). A similar principle applies to fecal streptococcus-enterococcus indicator selection (Report 1998). Initial verification of presumptive results for any of these special procedures is essential, using other procedures to establish test validity and to eliminate false-positive results that may break through the recovery protocol (Lin 1974).

Sample integrity is essential. Care must be exercised to collect samples representative of water use and to ensure that the sample does not become contaminated at the time of collection or before examination. Samples should be refrigerated or placed in an insulated cooler and promptly transported to the laboratory. Sample transit time limits for total coliform analysis of drinking water have been established at 24 h to limit any drastic changes in indicator occurrence impacted by antagonistic factors found in polluted natural waters. Sample processing within 8 h of collection should always be a goal for optimum recovery of organisms of significance. A dechlorinating agent (sodium thiosulfate) should be in the sterile sample bottle used to collect treated water supply or wastewater samples that often contain varying concentrations of disinfectant residues.

Heterotrophic bacteria

Heterotrophic bacteria are a diverse group of organisms. They encompass differences in morphology, gram-staining response, and biochemical reactions, but most of these organisms utilize carbon, nitrogen, phosphorus, and various trace elements necessary for the synthesis of living cell materials. The metabolic pathways to achieve these conversions are remarkably diverse, from those that use only inorganic sources of carbon, nitrogen and inorganic salts, to others that grow only when there are complex organics available. Such is the case for *Legionella* spp., which have fastidious nutrient requirements that are only made available in the metabolic biproducts from other bacteria in the aquatic community. Different groupings can be formed from this population of heterotrophs such as those that are pigmented (Reasoner et al. 1989), those that are antagonistic to coliform bacteria (Geldreich et al. 1978), and others that cause taste and odors (Burman 1965). Some of these bacteria are also known to be involved in plasmid transfers of R factors for antibiotics (Armstrong et al. 1982) or disinfection resistance (Ridgway and Olson 1982).

Predominate heterotrophic bacterial genera include *Acinetobacter*, *Aeromonas*, *Alcaligenes*, *Bacillus*, environmental coliforms (*Citrobacter*, *Enterobacter*, *Klebsiella*, *Escherichia*), *Flavobacterium*, *Pseudomonas*, *Micrococcus*, and *Moraxella*. Densities of heterotrophic bacteria in drinking water may be in a range from <10/ml to as high as 10 000/ml, while in raw sewage and food-processing wastes discharged to surface waters, densities may be in the millions per milliliter. In high-quality natural waters (protected ground water and springs) most of the organisms are indigenous and of no sanitary significance. In surface water (lakes and rivers), the heterotrophic composition will have varying inputs of contamination from stormwater runoff, domestic and industrial wastes, agricultural activities, wildlife habitation, soil contact, vegetation, and airborne pollutants.

Since the beginnings of bacteriology, the heterotrophic plate count has been used in an attempt to characterize water quality. Obviously, an excellent water was thought to have few bacteria per milliliter, whereas water with more than 1 000 bacteria per milliliter was considered of poor quality. In time, it was concluded that the general density of bacteria in water often had

Table 9 *Effect of incubation temperature and time to recover heterotrophic bacteria from water supply samples by different methods*

Temperature (°C)	Medium	Method	Incubation time (days)			
			2	4	6	7

	M-HPC	Membrane filter	32	140	150	150

Data revised from Reasoner (1990).

little specific relationship to increased health risks and should be replaced by a search for organisms more specific to fecal contamination (Bartram et al. 2003). Characterization and interpretation of heterotrophic bacterial densities now places the focus on using the information to identify changes in the microbial quality of distribution water caused by accumulating pipeline sediments and subsequent loss of a protective disinfectant residue. Most often these organisms are not of immediate public-health significance but upon amplification in a protected pipe habitat become the source of customer complaints of offensive taste/odors or emerge as an opportunistic pathogenic threat to some segment of the population.

Traditionally, most water-plant laboratories have used a nutritive standard plate count (SPC) agar or equivalent formulations for years from which they can provide an extensive database on heterotrophic bacterial densities in various water treatment processes. More recently, the trend is to use a dilute but diverse nutrient formulation such as R-2A agar, which contains a diverse variety of biodegradable materials (peptone, casamino acids, glucose, soluble starch, and sodium pyruvate). Colony densities are often many times greater and consist of a more diverse variety of organisms, including pigmented bacteria (Reasoner and Geldreich 1985). To achieve this improvement, incubation for 5–7 days at a temperature of 28°C is preferred rather than the more conventional time of 48 h at 35°C. This change in cultivation provides more opportunities for the growth of slow-generating bacteria, stressed organisms, and those species that have unique nutrient requirements. Since pour plates limit the growth of obligate aerobes in agar and introduce the risk of heat shock from melted agar (Klein and Wu 1974), attention has turned to surface cultivation of bacteria by spread plate to optimize recovery of these sensitive bacteria.

The membrane-filter procedure provides another approach to surface cultivation of organisms. The unique advantage of this technique is that it permits the analysis of larger sample volumes of high-quality water containing too few organisms to be detected by a 1-ml sample. The only restrictions to the size of sample analyzed are turbidity and colony density on the filter surface.

Some indication of the impact of membrane filter surface cultivation in comparison with pour plates and spread plates can be seen in Table 9. Recovery densities are significantly better on spread plates than by the traditional pour plate method because of agar temperature (Stapert et al. 1962). Limited surface area on the membrane filter for discrete colony formation without developing confluence with the other colonies thereby restricts extended incubation time and is the major drawback for achieving results equivalent to the spread plate technique.

Total coliform bacteria

In an effort to obtain a better focus on the sanitary quality of water, coliform bacteria soon supplanted the heterotrophic plate count as the most widely used indicator for routine analysis. Coliform bacteria consist of an artificial grouping of organisms believed to be associated with fecal pollution, but in reality they may also include environmental organisms from soil, vegetation, and decaying organic matter (Randall 1956; Geldreich et al. 1962; Schubert and Mann 1968). In the aquatic environment, environmental coliforms persist longer than do *E. coli*, the coliform constantly present in large numbers in feces from humans and other warm-blooded animals (wildlife, farm animals, cats, and dogs). Major members of these environmental coliforms include *Klebsiella*, *Enterobacter*, and *Citrobacter*. Although not

perfect, the total coliform concept continues to be a practical tool for providing basic microbial information on drinking-water treatment effectiveness and distribution system integrity.

Fecal coliforms/*E. coli*

Interest in further refining the total coliform group to exclude environmental coliforms, which are of no sanitary significance, led to the development of the fecal coliform (thermotolerant coliform) test based on lactose fermentation within 24 h at 44–44.5°C. The fecal coliform test proved to be a breakthrough with positive correlations of 93–99 percent to coliforms found in the feces of warm-blooded animals (Geldreich 1966).

In polluted waters, fecal coliform measurements relate more precisely to fecal contamination than to total coliforms and are significantly less susceptible to distortions caused by the regrowth characteristics of environmental strains in receiving waters. Essential factors that stimulate bacterial regrowth in polluted waters are nitrogen, carbon, and a warm water temperature (above 15°C). The regrowth phenomenon for fecal coliforms requires excessive nutrient discharges generally associated with poor treatment practices, particularly those used on some food-processing and paper-mill wastes.

Debate on the status of fecal *Klebsiella* and growth of the environmental component in the aquatic environment has led to attempts to search only for *E. coli*. Commercial biochemical kits for the identification of *E. coli* by detection of 4-methylumbelliferyl-β-D-glucuronidase (MUG) in either an amended medium or a chemically defined medium are now being used to further narrow the coliform group to one specific fecal organism – *E. coli*.

VERIFICATION OF COLIFORM BACTERIA

Verification of every positive coliform result is good laboratory practice that eliminates all doubts that the test results are perhaps caused by some analogous false reaction. Coliform analysis of drinking waters has revealed that as much as 30 percent of the samples having positive presumptive test results may also contain *Aeromonas* (Ptak et al. 1974; Leclerc et al. 1977). A few *Aeromonas* strains have been the cause of water-borne gastroenteritis (Moyer 1989), but most are saprophytic organisms in the aquatic environment. This situation illustrates the reason why test results must be confirmed to eliminate false-positive results in all methods even though this delay partly nullifies the rapidity of the results.

Rapid verification of coliform bacteria can be achieved in the demonstration of cytochrome oxidase and β-galactosidase activity. All coliform bacteria are negative for cytochrome oxidase while the enzyme β-glucuronidase appears to be highly specific for *E. coli*. This latter metabolic response has formed the basis of a rapid confirmatory test using the 4-nitrophenyl-β-D-glucuronide (Perez et al. 1986) or MUG (Report 1998).

Coliform speciation is a more in-depth verification process that has been used to demonstrate the equivalence of methods to detect all coliforms. Speciation as a verification tool has its greatest use in the identification of a coliform biofilm event and in further tracing for the existence of a microbial pathway in the water supply distribution system. In either case, further exploration of the original sample may provide information on fecal contamination that might not be present in a repeat sample collected the next day. Most often, repeat samples are negative because the contaminating event is of short duration (Geldreich 1996).

Fecal streptococci

Fecal streptococci are distinguished by their ability to grow at 45°C in the presence of 40 percent bile, and in the concentrations of sodium azide or potassium tellurite that are inhibitory to most coliforms organisms. Methods are available using agar pour plates (KF or PSE agars), multiple tube (azide dextrose broth), and membrane filter (KF agar or broth). The occurrence of fecal streptococci in water generally indicates fecal pollution (Geldreich and Kenner 1969). Although fecal streptococci rarely multiply in polluted waters, they may persist for extended periods in irrigation waters with high electrolyte contents and favorable temperatures (Geldreich 1973). There is also some evidence that *Enterococcus fecalis* (*Streptococcus fecalis*) multiplies in water from vegetable-processing plants (Mundt et al. 1966a). The reason for such contrasting responses is that the fecal streptococcus group includes a wide spectrum of strains that have specific fecal origins and diverse survival rates and includes several environmental biotypes (Mundt et al. 1962; Mundt and Graham 1968). Within the fecal streptococcus group, *Streptococcus bovis* and *Streptococcus equinus* are specific indicators of farm animal pollution. This differential characteristic is particularly useful in pollution investigations involving cattle feedlot runoff, farmland drainage, discharge from meat- and poultry-processing operations, and dairy-plant wastes (Geldreich 1972b). In addition, *S. bovis* and *S. equinus* are the fecal streptococci that die off most rapidly outside the animal intestinal tract. Therefore, the detection of these strains in water indicates very recent farm animal contamination. By contrast, the ubiquitous *E. fecalis* var. *liquifaciens* may affect precision of this indicator system at counts below 100 fecal streptococci per 100 ml, because at these low population levels this biotype generally predominates in high-quality natural waters. Fecal streptococcus counts greater than 100 per 100 ml, however, indicate significant fecal pollution derived from some warm-blooded animal source. The

densities for this indicator group in polluted waters approach the magnitude observed for coliforms, or at times exceed it by a factor of ten, depending upon the source of fecal pollution.

The density difference between fecal coliforms and fecal streptococci in fecal material is a unique relationship that can be useful in defining sources of pollution. The ratio of fecal coliform to fecal streptococcus in human feces and domestic wastes is greater than 4.0. The ratio of fecal coliforms to fecal streptococci in the feces of farm animals, cats, dogs, and rodents is less than 0.7. Such relationships between fecal coliform and fecal streptococci can only be developed from a fecal coliform medium (not an *E. coli* test) and from a fecal streptococcus medium such as KF or PSE agars (not from a medium dedicated to enterococcus). If cultivation of the more restrictive enterococcus subgroup is desired, mE agar or m-enterococcus agar may be considered.

Clostridium perfringens

The genus *Clostridium*, in particular *C. perfringens*, merits some attention as an indicator of fecal pollution because of its significant occurrence in feces (Bishop and Allcock 1960). *Clostridium* spp. spores are resistant to wastewater treatment practices and tolerant to extremes in temperature and environmental stress. *C. perfringens* is an indicator of present fecal contamination as well as a conservative tracer of past fecal pollution (Wilson and Blair 1925). *C. perfringens* has been used in the UK to monitor the quality of ground-water supplies that are examined infrequently, i.e. at intervals of 4–6 months (Wilson 1931). When *C. perfringens* is found in these well waters, sampling is repeated, possibly weekly, using total coliform or fecal coli measurements to search for intermittent fecal contamination and the need for a sanitary inspection to verify adequate well-head protection. The use of *C. perfringens* as a supplemental indicator to measure the efficiency of various water treatment processes has been proposed, but the greater abundance of total aerobic spore formers in raw water may be a more effective system in providing evidence of treatment barrier performance, particularly in reference to pathogenic protozoans(Rice et al. 1996).

The longer persistence of *C. perfringens* in the water environment creates a residual density of this organism, which can obscure the detection of low densities of recent polluting discharges to receiving waters. However, Bonde reported that *C. perfringens* densities in the sediment of marine waters were proportional to pollution discharges and the ratios of spores to vegetative cells of this bacterial species increased with distance from the pollution source (Bonde 1962, 1967, 1968). Thus, vegetative cells of *C. perfringens* may be expected to predominate in raw sewage.

Although *C. perfringens* is an anaerobic organism, it can tolerate up to 5 percent oxygen without significant loss in quantitative recovery (Fulton and Richardson 1971). Therefore, methodology has not been complicated by the restrictions of complete anaerobiosis. On sulfite–alum agar (to reduce available oxygen) incubated at 48°C, 79–100 percent of the black sulfite-reducing colonies recovered from a variety of waters were verified as *C. perfringens* (Bonde 1962). The other black colonies on this medium may be *Salmonella*, *Proteus*, *Bacteroides*, and sometimes *E. coli* (Johnston et al. 1964). This practical procedure has frequently been used to obtain a presumptive quantitation of *C. perfringens* in various fresh and marine waters and sediments. Another approach is to filter an appropriate volume of water sample through a membrane filter, place the membrane filter on a modified m-CP agar (Armon and Payment 1988), and incubate anaerobically for 24 h at 44.5°C. Upon exposure to ammonium hydroxide, the yellow to straw-colored *C. perfringens* colonies turn dark pink to magenta. Confirmation may be done by anaerobic growth in thioglycollate, a positive Gram stain reaction, and stormy fermentation of iron milk.

Pseudomonas species

Pseudomonads are ubiquitous bacteria that are able to flourish in a wide variety of habitats (surface waters, aquifers, seawater, soil, and vegetation). Some pseudomonads are among the prominent denitrifiers while others grow prodigiously in and on tertiary treatment devices such as reverse osmosis and electrodialysis membranes and in sand or carbon filtration beds. Pseudomonads reported in some drinking-water supplies include *Pseudomonas aeruginosa*, *Burkholderia cepacia* (*Pseudomonas cepacia*), *Pseudomonas fluorescens*, *Burkholderia mallei* (*Pseudomonas mallei*), *Stenotrophomonas maltophilia* (*Pseudomonas maltophila*), *Pseudomonas putida*, and *Comamonas testosteroni* (*Pseudomonas testosteroni*) (Geldreich 1990, 1996; Gambassini et al. 1990). To this list can be added *Pseudomonas stutzeri*, *Brevundimonas diminuta* (*Pseudomonas diminuta*), and *Delftia acidovorans* (*Pseudomonas acidovorans*), which have been found in bottled waters at densities ranging from 10^3 to 10^5 organisms per milliliter (Gavin and LeClerc 1974; Hernandez Duquino and Rosenberg 1987). These organisms metabolically adapt to survival on minimal nutrient concentrations typical of protected aquifers and treated drinking water. Routine enumeration of pseudomonads in water supply is not recommended but may be of value in certain industries, such as those manufacturing foods, drinks, and pharmaceutical products, where high-quality water is desirable. Monitoring the hospital building water-distribution system for *P. aeruginosa* is important because this organism is a major opportunistic pathogen

and its presence in this environment is a matter for concern.

PRINCIPLES OF PATHOGEN DETECTION

Detection of pathogens in the aquatic environment requires techniques to concentrate a few organisms from large samples and reduce the interfering flora of many heterotrophic bacteria that are certain to be a factor in contaminated water. For bacterial pathogens, this is generally accomplished through filtration of large volumes of water (1–2 l) followed by cultivation in selective media for suppression of coliforms and other heterotrophic organisms. Another approach is to place gauze pads in the polluted stream for 3–5 days to entrap the pathogenic agent, then express the water from the pad to selective enrichment media (Moore 1948, 1950). A third approach is to filter samples of 1–2 l through diatomaceous earth held in a membrane-filter (MF) funnel by an absorbent pad, and then place sections of the plug in appropriate media for cultivation and species identification.

STRATEGIES FOR RAPID METHODS

Rapid laboratory methods to better characterize water-supply quality are an urgent research priority. The inability of microbiology to provide data within a few hours of sample processing has been a major deterrent to greater utilization of the science in water-plant operations and in bathing-water monitoring. With the discovery that disinfection byproducts may contribute carcinogens and possibly other toxins to the water supply, treatment schemes are being modified to minimize these undesirable formations. In so doing the effectiveness of treatment barriers required to avoid microbial contaminant passages becomes a matter of greater concern. Consequently, the need for rapid assessment of water quality is more urgent than ever before. Such information would also be of singular value as an aid in restoring the quality of drinking water after contamination caused by sudden source-water-quality deterioration, treatment failures, distribution line breaks, poor practices in disinfection line repair, and sudden occurrence of cross-connections.

Any breakthrough in the development of rapid tests must involve specificity, sensitivity, and precision with achievement of a test result within a few hours. Searching for rapid methods in environmental microbiology has revealed a variety of candidate methods that have potential in real-time monitoring (Geldreich and Reasoner 1985). As might be anticipated, rapid tests that can be performed in less than 1 h have little specificity and may possibly include nonviable cells. These limitations are being solved, but the tradeoff is in the need for more costly materials and instrumentation sensitive to trace concentrations of specific metabolic products produced by organisms of interest. One exception to this trend may be seen in a direct membrane-filter method incorporating MUG in a modified medium (M-7h agar), which provides detection of as few as one fecal coliform per 100 ml in 6 h (Berg and Fiksdal 1988).

Efforts to shorten the time required to detect bacterial indicator systems or individual pathogen species in a water sample flora to less than 5 h will require instrumentation capable of detecting viable organisms directly or after a brief period of amplification in a selective enrichment medium. Instrumentation and test materials for these methods will become more readily available to the laboratory in the near future.

Of the rapid test candidates currently in development, gene probes appear to be the most promising (Richardson et al. 1991). Research into microbial genetics has led to techniques that can detect minute quantities of nucleotide sequences unique to a single species of organism, whether bacteria, fungi, virus, or invertebrates. For example, ten enterotoxigenic *E. coli* per milliliter of canal water were detected in the grossly polluted canals in Bangkok, Thailand, by using gene-probe technology (Mosely et al. 1982).

The use of gene probes and automated microbiological techniques will become a major activity in the water plant laboratories of the future (Geldreich 1991). Perhaps development of multiplex probes to detect bacterial pathogens or enteroviruses will become sensitive enough to detect one organism per liter of sample within an hour. At the present time, some probe tests can be completed in 0.5–2 h, but they often require prior culture amplification for 7–18 h to achieve organism densities at levels where acceptable probe detection is possible (Tenover 1988; Report 1998).

Bacteriology of milk and milk products

FREDERICK J. BOLTON

Milk	1	Ice cream	22
Milk powder	17	Cheese	23
Cream	20	Acknowledgments	29
Yogurt	20	References	29
Butter	22		

The milk of cows, buffaloes, sheep, goats, donkeys, horses, and camels has been an important item of human food for centuries. Pathogenic microorganisms often contaminate milk, which has been recognized as a vehicle for disease since the late nineteenth century (Department of Public Health 1886). Strategies such as improved hygiene, eradication of tuberculosis and brucellosis from cattle, and heat treatment are now employed in most developed countries to reduce the risk to human health. Liquid milk and milk products such as cheese, yogurt, and fermented milks are often stored for days, weeks, or months and finally consumed without cooking. It is not surprising, therefore, that these items are still implicated in major outbreaks of food poisoning and other communicable diseases (Djuretic et al. 1997; De Buyser et al. 2001; Gillespie et al. 2003a).

Because milk and milk products are such universal items of food, sporadic infections caused by them may go unnoticed. Wilson (1942) discussed the difficulties of ascertaining the frequency of milkborne disease. At that time, pasteurization was not widely practiced, and both milk-associated tuberculosis and undulant fever were major public health problems. Both diseases had long incubation periods, gradual onset, and variable infectivity. It was therefore difficult to prove their relationship with the consumption of milk. Moreover, if, in large explosive outbreaks of disease such as typhoid fever, scarlet fever, or food poisoning, cases were scattered over a wide area, other sources of infection were often suspected. Thus, unless careful epidemiological investigations were made, the association with contaminated milk might be overlooked. Even nowadays, in developing countries, Wilson's observations remain true and where hygiene is poor and animal disease uncontrolled, milk is an important vehicle for various human diseases.

Most developed countries have sophisticated disease surveillance systems in place and resources to investigate outbreaks. In addition, the pathogenic microorganisms likely to contaminate milk differ from those prevalent in 1942 (Bell and Palmer 1983; Milner 1995; Djuretic et al. 1997; De Buyser et al. 2001; Gillespie et al. 2003a); some have decreased as a result of animal disease eradication programs and changes in patterns of human disease, but others have taken their place. It is clear that, although rare, public health problems with milk and milk products remain and where milk products are produced by large commercial establishments there is potential for a major outbreak should anything go wrong.

MILK

Microbiology of cows' milk

The major milk-producing animal is the cow and most of the available information and research into microbiology of milk relates to cows' milk. Microorganisms in raw milk are derived from various sources, including the commensal or pathogenic flora of the udder, teat canals, and skin, which varies depending on whether cattle are housed under cover or in yards or are out in pasture; fecal contamination; and environmental sources such as

milking equipment, storage vessels or the water supply. Commensal or pathogenic organisms from the milkers may also contribute.

The importance of particular organisms depends on whether the milk is to be consumed raw or after heat processing, and on the temperature and duration of storage. In developed countries the commercial production of milk is subject to strict regulations regarding hygiene and refrigeration during transport and storage. The keeping quality and flavor of the heat-treated product is adversely affected by psychrotrophic bacteria (capable of growing at between 2 and 7°C), thermoduric organisms, and post-pasteurization contamination. Some of the enzymes produced by psychrotrophs are heat-tolerant and cause spoilage both before and after pasteurization. Post-pasteurization contamination is the most important factor influencing the quality of pasteurized milk but the quality and hygiene of raw milk also have important effects on the quality of the heat-treated product.

No matter how good the health of the dairy herd, the milking hygiene, and the storage conditions, the safety of raw milk cannot be guaranteed (Sharp et al. 1985; Maguire 1993; de Louvois and Rampling 1998; Jayarao and Henning 2001; Gillespie et al. 2003a). Detailed reviews of the microbiology of raw milk are to be found in specialist publications (Bramley and McKinnon 1990; Gilmour and Rowe 1990). Most of the microorganisms in hygienically produced raw milk with low bacterial counts are derived from the normal flora of the cow's teat canals and skin, and comprise coagulase-negative staphylococci, micrococci, and streptococci. Streptococci belonging to Lancefield group N cause natural souring of raw milk. Commercially cultured strains of these organisms are used as cheese starters in the dairy industry.

The skin of the teats and udder inevitably becomes contaminated by fecal and environmental bacteria, viruses, yeasts, and molds. Cows housed inside during winter have very heavily soiled udders and the bacterial counts in milk are high even after washing the teats. The most effective way of removing contamination is careful washing followed by drying with paper towels or with a disinfectant impregnated cloth. When the cattle are turned out to pasture there is a pronounced decline in the total bacterial count in bulk milk, even compared with milk from carefully washed cows (Bramley and McKinnon 1990). Inadequately disinfected milking machines, pipes, and tanks are also important sources of post-milking contamination with bacteria, which are mainly derived from milk previously in the system. In the UK, the water supply to all areas concerned with milking and milk collection must be potable, but in many countries farms obtain water from boreholes or springs which may at times be contaminated with pathogenic organisms such as *Campylobacter jejuni*, verocytotoxin producing *Escherichia coli* or *Salmonella* serotypes. Contaminated water can also be a source of psychrotrophic organisms such as *Pseudomonas* spp., which cause spoilage of refrigerated milk. Under modern systems of dairy management and marketing, milk is stored in refrigerated farm tanks for up to 48 h prior to collection. Once at the creamery, it may again be stored overnight in large insulated or refrigerated silos. During this time there is considerable scope for multiplication of psychrotrophic organisms.

The level of bacteria in raw milk increases significantly if the cow has mastitis and many of the organisms associated with this condition are potential causes of human infection or intoxication. The most common causes of mastitis are *Staphylococcus aureus* (including enterotoxigenic strains); *Streptococcus agalactiae* (Lancefield group B); *Streptococcus uberis*; *Streptococcus dysgalactiae* (Lancefield group C); and *E. coli*. Less common causes are *Leptospira interrogans* serovar. *hardjo*, *Streptococcus zooepidemicus* (Lancefield group C), *Listeria monocytogenes*, *Bacillus cereus*, *Pasteurella multocida*, *Clostridium perfringens*, *Nocardia* spp., *Cryptococcus neoformans*, *Actinomyces* spp., and *Corynebacterium ulcerans*.

At one time, *Mycobacterium* spp. were an important cause of bovine mastitis in the UK and both *Mycobacterium bovis* and *Brucella abortus* were commonly present in milk even in the absence of mastitis (Galbraith and Pusey 1984). Both these pathogens are now virtually eradicated from cattle in most developed countries. Milkborne scarlet fever due to *Streptococcus pyogenes* (Lancefield group A) was also common at one time (Eyler 1986). Group A streptococci are not natural pathogens of cattle but cows can develop teat lesions and mastitis if infected by a human carrier. Other pathogens such as *L. monocytogenes*, *Coxiella burnetii*, and *S. zooepidemicus* may on occasions be excreted in milk in the absence of udder disease and *Salmonella* serotypes (Marth 1969) and *C. jejuni* occasionally cause clinical or subclinical mastitis (Morgan et al. 1985; Orr et al. 1995). Under natural conditions, fecal contamination is probably the most common source of salmonellae, *L. monocytogenes*, *C. jejuni*, and verocytotoxin producing *E. coli* O157.

A study conducted by the Public Health Laboratory Service (PHLS) in 1996–1997 showed that 41 of 1 097 samples of bottled raw milk were contaminated with potentially pathogenic organisms (de Louvois and Rampling 1998). Of these 41 samples, five contained *Salmonella* serotypes, three *E. coli* O157, 19 *C. jejuni*, 12 *S. aureus*, and two hemolytic streptococci. This study also confirmed that pathogens may be present in raw milk that satisfies other statutory criteria. In a study of bulk tank milk sampled from 131 dairy herds in South Dakota and western Minnesota, USA, 26 percent of samples contained one or more foodborne pathogens (Jayarao and Henning 2001). In this latter study *C. jejuni*, verocytotoxin producing *E. coli*, *L. monocytogenes*, *Salmonella* spp., and *Yersinia enterocolitica*

were detected in 9.2, 3.8, 4.6, 6.1, and 6.1 percent of bulk tank milk samples, respectively. *E. coli* O157 was not detected in bulk tank milk samples in this study. These studies confirm that fecal contamination of raw milk and presence of potential pathogens in raw milk is a frequent event.

Microbiology of ewes' and goats' milk

Milk, and in particular milk products, made from ewes' and goats' milk have become very popular in recent years and the commercial market for cheese and yogurt is expanding. Surveys of the microbiological quality of goats' milk have been performed in Scotland (Hunter and Cruickshank 1984) and England (Roberts 1985; Little and de Louvois 1999). The 1984 and 1985 studies both showed that high standards of hygiene were possible but that problems arose from inadequate disinfection of milking equipment or from inadequate control of storage temperatures at the point of sale.

A study of goats' milk on six farms in Quebec over a one year period showed that the levels of aerobes, psychrotrophs, coliforms, yeasts, and molds increased during the summer months but that this could be controlled by good hygiene, rapid cooling, refrigeration, and frequent collections by refrigerated vehicles (Tirard-Collet et al. 1991). Somatic cell numbers were also measured and these confirmed that, in contrast to the finding with cows, variation with the season and the state of lactation of the animals, high levels of somatic cells were not necessarily an indication of mastitis (Hinckley 1991).

A more recent study undertaken by the Public Health Laboratory Service assessed the microbiological quality of unpasteurised goats' milk sold at retail (Little and de Louvois 1999). Although this was a pilot study, the results indicate that 47 percent (47/100) of goats' milk samples failed to meet the standards required in the Dairy Products (Hygiene) Regulations (HMSO 1995). *C. jejuni*, *E. coli* O157, and *Salmonella* spp. were not detected but *S. aureus*, hemolytic streptococci or enterococci were present in excess of 100 cfu/ml in 6, 2, and 12 percent of samples, respectively.

There are very few publications on the microbiology of sheep milk. Studies in Spain, Bulgaria, and Norway have indicated that significant contamination with Enterobacteriaceae and coliforms may occur during milking and as a result of poor cleaning practices on the farm (Gaya et al. 1987). A very limited study of ewes' milk was reported by Little and de Louvois (1999), and demonstrated that 50 percent (13/26) of ewes' milk failed to meet the standards required in the Dairy Products (Hygiene) Regulations (HMSO 1995). *C. jejuni*, *E. coli* O157, and *Salmonella* spp. were not detected, but *S. aureus*, or enterococci were present in excess of 100 cfu/ml in 11.5 and 27 percent of samples, respectively.

Even when hygiene is good, the risk of milkborne infection from unpasteurized goats' or ewes' milk is similar to that for cows' milk. *Brucella melitensis* and *Brucella ovis* are still common in goats and sheep in the Mediterranean countries, Asia, and Latin America and human infections are associated with the consumption of raw milk or cheese made from unpasteurized milk (Wallach et al. 1994; Report 1995). Other pathogenic microorganisms such as *Salmonella* Typhimurium, *S. aureus*, *Y. enterocolitica*, *C. perfringens*, *B. cereus*, and *C. jejuni* can survive in goats' milk under experimental conditions, and some of these pathogens multiply at temperatures of 22°C or more (Roberts 1985). Outbreaks and incidents of brucellosis, campylobacter infection, salmonellosis, viral tick-borne encephalitis, Q fever, staphylococcal food poisoning, and *C. ulcerans* sore throat have been associated with consumption of untreated goats' milk or goat cheese in Canada, Britain, and the USA (Hutchinson et al. 1985a; Sharp 1987; Fishbein and Raoult 1992; Report 1994a, 1995). There is also a high incidence of toxoplasma infection in goats (Skinner et al. 1987) and there is convincing evidence that consumption of unpasteurized goats' milk can transmit infection to man (Sacks et al. 1982). *E. coli* O157 has emerged as a significant pathogen in milk and dairy products and outbreaks associated with cheese made from unpasteurized goats' milk have been reported from the Czech Republic (Bielaszewska et al. 1997) and from Scotland (Curnow 1999). Both of these outbreaks were associated with infection in children. The outbreak in the Czech Republic was recognized because of a cluster of four cases of hemolytic uremic syndrome. The outbreak in Scotland resulted in 22 confirmed cases of infection in children attending a primary school. The most recent outbreak of *E. coli* O157 associated with unpasteurized goats' milk was reported in British Columbia, Canada (McIntyre et al. 2002). Following a review of infection with *E. coli* O157 in England and Wales and Scotland, it has been recommended that raw ewes' and goats' milk for sale for drinking should be heat treated (Task Force on *E. coli* O157 2001).

Sheep can also carry many microorganisms pathogenic for man, such as *Salmonella* spp., *C. burnetii*, *Campylobacter* spp., *E. coli* O157, *S. aureus*, *Toxoplasma gondii*, and *L. monocytogenes*. *S. aureus* seems to be a common contaminant of both ewes' and goats' milk and more prevalent than in cows' milk (Valle et al. 1990). A high proportion of isolates produce enterotoxin. An outbreak of staphylococcal food poisoning in Scotland was traced to cheese made from unpasteurized sheep milk (Sharp 1987). Although *L. monocytogenes* is a cause of meningoencephalitis in sheep and may also be excreted in the milk and feces of healthy sheep, the risk of contamination of ewes' milk on the farm does not seem to be any greater than for cows' milk. Rodriguez et al. (1994) sampled milk from 1 052 farm bulk tanks on 283

Spanish farms throughout a 1-year period and found that *Listeria* spp. could be detected in 4.56 percent and *L. monocytogenes* in 2.19 percent. This low prevalence was confirmed in the study described by Little and de Louvois (1999). *Listeria* species were not detected by enrichment culture in all 26 samples of ewes' milk and 100 samples of goats' milk. Therefore, the risk of acquiring *L. monocytogenes* infection from these products appears to be low.

Heat treatment of milk

PASTEURIZED MILK

The international definition of pasteurization (Report 1994b) is: 'A heat treatment process applied to a product with the aim of avoiding public health hazards arising from pathogenic microorganisms associated with milk. Pasteurization as a heat treatment process is intended to result in only minimal chemical, physical, and organoleptic changes.' The process was originally introduced by dairies to improve the keeping quality of milk (Wilson 1942). It soon became clear that heat treatment would also destroy pathogenic organisms such as tubercle bacilli and hemolytic streptococci. The public health aspects of the process then assumed the greater importance.

Several time–temperature combinations are effective. The Dairy Products (Hygiene) Regulations (HSMO 1995) for England and Wales state that milk shall be pasteurized by means of a heat treatment involving a high temperature for a short time (at least 71.7°C for 15 s, or any equivalent combination) or a pasteurization process using different time and temperature combinations to obtain an equivalent effect. The product must give a negative alkaline phosphatase test immediately after heat treatment and be cooled as soon as practicable to a temperature of 6°C or lower and stored at or below that temperature until it leaves the treatment establishment.

The high temperature short time (HTST) method is most commonly used both in large commercial dairies and on farms. The HTST plant consists of a plate heat exchanger and a holding tube (Figure 1). Raw milk

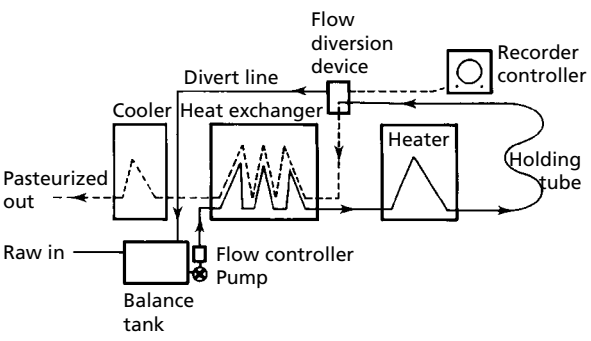

Figure 1 *Diagrammatic representation of milk flow through HTST pasteurizer*

enters the heat exchanger and is warmed by the hot milk leaving the hot section along the other side of the plates. The warmed milk is then heated to the statutory temperature before it runs through the holding tube for at least 15 s. The hot milk then re-enters the heat exchanger, being cooled initially by cold raw milk, then by tap water and finally by chilled water. The law requires that any HTST system has an automatic temperature control and a safety device that automatically diverts milk back for reheating if it has not been raised to the statutory temperature. In addition, there must be indicating and recording thermometers on the plant and an automatic recording device for the safety system.

An alternative method for small quantities of milk is the holder or batch-heating process in which milk is heated to between 62.8 and 65.6°C and held at that temperature for 30 min, followed by rapid cooling to below 10°C. The heating vessel incorporates an insulated outer jacket through which the heating and cooling media can flow, an agitator to ensure uniform heating, thermometers, including a recording thermometer and a temperature control device that automatically regulates the heating of the milk to pasteurization temperature and the subsequent retention at this temperature for the holding period (Report 1994b). Nowadays, the holder or batch method is seldom practiced for the pasteurization of milk but is still used in some small on-farm dairies for the pasteurization of cream.

The combinations of time and temperature used for the heat treatment of milk are designed to kill all pathogenic vegetative cells including *C. burnetii* which is relatively heat-resistant (Zall 1990). Bacterial spores and some preformed bacterial or fungal toxins, however, are not destroyed by pasteurization temperatures. The keeping quality of pasteurized milk depends both on the quality before heat treatment and on the amount of post-pasteurization contamination. Thermoduric bacteria that survive pasteurization belong to the genera *Bacillus*, *Clostridium*, *Corynebacterium*, *Micrococcus*, *Streptococcus*, and *Lactobacillus*. The importance of thermoduric organisms depends on the storage temperature. Some thermoduric fecal streptococci, *Bacillus* spp. and *Clostridium* spp. can grow below 7°C and are therefore also psychrotrophic. Most thermoduric organisms are mesophilic with optimum growth between 20 and 32°C. If pasteurized milk is allowed to remain at ambient temperature for several hours, as commonly happens with doorstep deliveries, growth of mesophilic bacteria such as *B. cereus* will soon cause bitterness, sweet curdling, and 'bitty' cream. Contamination with *B. cereus* is very common and yet reports of bacillus food poisoning due to the consumption of milk or cream are rare (Gilbert 1979; Christiansson 1992). This is probably because enterotoxin is not usually produced by *B. cereus* until the concentration of organisms is so high and consequent spoilage so great that the milk is unusable.

The lactic acid-producing streptococci do not survive pasteurization and 'souring' does not therefore take place in pasteurized milk. Repasteurization of returned milk results in enrichment of the thermoduric organisms in the final product and so is bad practice.

The keeping quality and flavor of properly refrigerated pasteurized milk depends on the types and numbers of psychrotrophic organisms. The most important of these are species of *Pseudomonas*, *Flavobacterium*, *Alcaligenes*, *Acinetobacter*, yeasts, and molds. These organisms are not thermoduric but are derived from the post-pasteurization environment. They outgrow any thermoduric psychrotrophs that may be present, and for this reason, hygiene of the pipes, tanks, and bottle fillers is the most important factor influencing the keeping quality of milk stored below 10°C (Schröder 1984). Psychrotrophic organisms are responsible for various 'off' flavors, ropiness, and changes in color.

ULTRA-HEAT-TREATED MILK

According to the Regulations, the description ultra-heat-treated (UHT) may be applied to a continuous flow of milk that has been heated to a temperature of not less than 135°C and retained at that temperature for at least 1 s. The method of heating may be indirect or by direct injection of steam. After treatment, the milk must be packaged in sterile airtight containers that are filled and sealed with aseptic precautions. In practice, the milk is usually heated to more than 140°C for 2–4 s to produce 'commercial sterility' – which means that it has a shelf-life of several weeks because, although small numbers of spores may survive, they are usually unable to grow under the conditions of storage (Lewis 1994).

STERILIZED MILK

The term 'sterilized' is applied to milk that has been filtered, clarified, homogenized, and then heated to 100°C for long enough to denature all casein and whey proteins. Traditionally, sterilized milk is bottled and sealed before heating to 110–116°C for 20–30 min. The process inevitably results in a caramelized flavor and brownish color but this is popular with some consumers.

THERMIZED MILK

In situations where raw milk has to be held under chilled conditions for some time, its keeping quality can be improved by a low temperature heat treatment called thermization. Thermized milk must conform to strict definitions according to European law. It must be obtained from raw cows' milk which, if it is not treated within 36 h of acceptance by the establishment, has a plate count at 30°C prior to thermization which indicates a concentration of 3×10^5/ml or less. The thermization treatment consists of heating raw milk for at least 15 s at between 57 and 68°C so that, after such treatment, the milk still shows a positive reaction in the phosphatase test. This treatment is not sufficient to eliminate pathogenic microorganisms.

Legislation

In most developed countries, the hygiene and composition of milk and milk products are subject to statutory controls, which specify general standards for production, transport, and processing, and specific standards, which set microbiological and chemical limits for each product.

Council Directive 92/46/EEC (as amended) applies to milk from sheep, goats, buffaloes, and cows and covers milk and milk products produced within the European Union. Detailed microbiological standards including absence of pathogenic microorganisms are specified for raw milk, heat-treated milk, and milk-based products, which must be sampled at the production or processing establishments. Nonmicrobiological tests are also specified, including somatic cell count, which is an indicator of mastitis in raw milk from cows and buffaloes (no such standard is specified for milk from sheep and goats because the levels are subject to wide natural fluctuations in these animals), and the phosphatase and peroxidase test for pasteurized milk. Greenwood and Rampling (1995) list the microbiological standards and guideline criteria specified in the Dairy Products (Hygiene) Regulations (HMSO 1995), for England and Wales based on the European Directive (92/46/EEC). Greenwood (1995) has produced details of appropriate methods for the microbiological tests and the phosphatase and peroxidase tests.

Similar standards apply in the USA for milk and milk products from sheep, goats, and cows. The US Food and Drug Administration produces a model code for grade A milk which is specified in the Pasteurized Milk Ordinance and the Dried Milk Ordinance. These cover production, transport, and processing, as well as microbiological and chemical tests. Grade A standards are applicable to all products that are produced in plants that produce milk for shipment between states (more than 95 percent of fluid milk products). Milk is produced on the farm as either 'grade A' or 'manufacturing grade' but most milk for manufacture of dairy products is surplus grade A that has not been sold as liquid milk for drinking. The production of 'manufacturing grade' milk and of products such as cheese, butter, and ice cream is subject to regulatory oversight by the US Department of Agriculture.

QUALITY CONTROL TESTS

The plate count at 30°C and the coliform count form the basis of microbiological quality control tests for milk and milk products in most countries, including the USA. In Europe the plate count at 21°C after pre-incubation at 6°C for 5 days has been adopted as the statutory test for pasteurized milk. This test was designed to assess the

level of psychrotrophic bacteria and thus keeping quality, but it has been subject to much criticism because it is time-consuming, expensive to perform, and has poor reproducibility (Scotter et al. 1993).

The coliform count is universally adopted as an indicator of poor hygiene and of post-pasteurization contamination. High counts in pasteurized milk may also be due to faults in the pasteurizer or contamination of pasteurized milk with raw milk. Pasteurization plants that produce milk which fails this test repeatedly, in spite of attention to cleaning and disinfection routines, should be examined carefully for leaks in the pasteurizer or faulty operation of the plant.

The absence of detectable alkaline phosphatase is the most important test to demonstrate adequate heat treatment of pasteurized milk or cream. Alkaline phosphatase is normally present in raw milk and is destroyed by heat treatment at a temperature slightly above that required to destroy *Mycobacterium tuberculosis* and slightly lower than those employed in the pasteurization of milk. Detection of phosphatase in pasteurized milk may therefore indicate inadequate heat treatment or contamination with raw milk.

There are several internationally recognized methods of testing that may be used for enforcement purposes (Rocco 1990). The statutory test in the Dairy Products (Hygiene) Regulations (HSMO 1995) is an analytical method based on the use of phenyl phosphate as the substrate. Milk that is satisfactorily pasteurized should liberate no more than 4 μg of phenol during a 1 h period. This is equivalent to the presence of 0.1 percent raw milk in pasteurized milk (Greenwood and Rampling 1997). A fluorimetric method is now available commercially which reports results in mU/l of fluorescent substrate released. A reading of 500 mU/l is equivalent to the presence of 0.1 percent raw milk, the statutory test limit of the previously mentioned statutory analytical method. The fluorimetric method is able to detect the equivalent of 0.006 percent raw milk in pasteurized milk and because of this increased sensitivity, it is recommended that a value of less than 100 mU/l should be used as an indicator of effective pasteurization and hence of microbiological safety (Greenwood and Rampling 1997).

It should be noted that not all of the alkaline phosphatase tests have the sensitivity to detect the presence of low levels of raw milk contamination due to small leaks in valves or heat exchange plates. To monitor the process efficiently, the test should be applied to samples taken from the cold milk exit side of the pasteurizer and immediately following an episode of flow diversion to check the integrity of the flow diversion valve.

Alkaline phosphatase in pasteurized milk may be due to any or a combination of residual, microbial, or reactivated alkaline phosphatase. The presence of residual phosphatase indicates inadequate pasteurization or post-pasteurization contamination with raw milk. Microbial phosphatase can occur when the milk has been stored for a long period of time before pasteurization and is the result of psychrotrophic bacteria growing and producing a heat stable alkaline phosphatase that survives the pasteurization process. Reactivated phosphatase may occasionally occur, particularly with cream. Reactivation is mediated by a heat-stable activator in the presence of magnesium and β-lactoglobulin (Lyster and Aschaffenburg 1962). The degree of reactivation depends on the initial concentration of phosphatase and, since the enzyme is adsorbed to the phospholipid of the fat globule membrane, it varies with the amount of fat and is greatest in cream. Statutory phosphatase tests for cream include a test which distinguishes between native (residual) and reactivated phosphatase.

The peroxidase test is a test for excessive heat treatment. If milk is subjected to significantly higher temperatures than those used for standard pasteurization, inactivation of the enzyme will occur. Thus a positive peroxidase test indicates that milk has not been overheated.

RESTRICTIONS ON THE SALE OF UNPASTEURIZED MILK

Most milk for drinking and for the manufacture of milk products is pasteurized but few countries have formal restrictions on the sale of raw milk. In the USA, however, very few milk products can be sold in the unpasteurized state. Some states allow limited sale of raw fluid milk and some hard cheeses may be manufactured from raw milk (Childer R.N., personal communication 1996). In England and Wales, legislation enacted in 1985 and 1986 limited sales of unpasteurized cows' milk to sales by farmhouse caterers, from farm gates, and from local retail deliveries of milk bottled on the farm. In Scotland, legislation in 1983 and 1986 prohibited all sale of unpasteurized cows' milk and cream. There are no restrictions on the sale of raw liquid milk from goats, sheep, or buffaloes or on any milk products made from raw milk anywhere in the UK and no restrictions on the sale of any unpasteurized milk or milk products elsewhere in Europe.

Outbreaks and incidents of infection associated with milk

A recent review of bacterial foodborne disease in France and six other countries estimated that outbreaks associated with milk and dairy products accounted for 1–5 percent of all foodborne outbreaks (De Buyser et al. 2001). A recent review of 69 milk and dairy product associated outbreaks in France during the period 1992–1997 confirmed that 87 percent were linked with cheese, 10 percent with milk, and 3 percent with other products. *S. aureus* was the major problem accounting for 85.5 percent of the outbreaks. Raw milk and raw milk products accounted for 48 percent of the 69 outbreaks. The situation is different in England and Wales where

most of the outbreaks are associated with liquid milk and fewer with dairy products. Milk and dairy products account for 2.5 percent (46/1774) of all foodborne outbreaks in England and Wales (Gillespie, I. CDSC, personal communication). Milkborne outbreaks in England and Wales account for 1.5 percent of all foodborne outbreaks (Gillespie et al. 2003a).

In the UK most outbreaks of infection due to the consumption of liquid milk continue to be caused by pathogens associated with the gastrointestinal tract of animals. *E. coli* O157, *Salmonella* spp. or *C. jejuni* are most prevalent. There have also been incidents due to less common animal-associated organisms such as *Y. enterocolitica*, *L. monocytogenes*, *S. zooepidemicus*, *Streptobacillus moniliformis*, *C. ulcerans*, and *Cryptosporidium parvum*. Table 1 lists outbreaks of infection associated with milk and milk products in England and Wales from 1992 to 2000. In comparison to the data summarizing outbreaks in England and Wales from 1989 to 1994 (Rampling 1998) there has been a significant change in that verocytotoxin producing *E. coli* O157 has emerged as the major cause of outbreaks associated with milk and dairy products. In spite of legislation limiting sales, and even though less than 3 percent of the total milk production is unpasteurized in England and Wales, 53 percent of outbreaks continue to be caused by the consumption of raw milk.

On the other hand, the situation is different in Scotland where, in the face of the epidemiological, microbiological, and research evidence that heat treatment of all cows' milk would be cost-effective, the retail sale of untreated cows' milk was prohibited from August 1983. Thereafter, incidents of infection related to milk were controlled in the general community but a small number persisted in the farming community where farm workers and their families received untreated milk as

Table 1 *Milk- and milk product-associated outbreaks and incidents of infection; reports to the Health Protection Agency Communicable Disease Surveillance Centre, England and Wales 1992–2000*

Year	Organism	Vehicle of infection	Number of persons infected	Evidence
1992	*Salmonella* Enteritidis PT4	Ice cream	7	S
	Salmonella Enteritidis PT4	School milk[a]	44	D
	Campylobacter jejuni	Sold as pasteurized milk	110	S
	Campylobacter jejuni	Raw milk	72	S
1993	*Salmonella* Typhimurium	Raw milk	13	M, D
	Escherichia coli O157	Raw milk	11	M
	Campylobacter jejuni	Raw milk	22	D
1994	*Salmonella* Typhimurium	Raw milk	11	M
	Salmonella Typhimurium	Raw milk	4	M, S
	Salmonella Typhimurium	Sold as pasteurized milk	26	M
	Campylobacter jejuni	Raw milk	23	S
	Streptococcus zooepidemicus	Raw milk	4	M
1995	*Salmonella* Typhimurium	Raw milk	26	M, D
	Campylobacter jejuni	Milk[a,b]	12	S
	Campylobacter jejuni	Raw milk[b]	35	S
	Cryptosporidium spp.	Sold as pasteurized milk	52	S
1996	*Salmonella* Typhimurium	Raw milk	5	M
	Escherichia coli O157	Sold as pasteurized milk	12	D
	Escherichia coli O157	Sold as pasteurized milk and raw milk	6	M
	Campylobacter jejuni	Raw milk	5	S
1997	*Salmonella* Anatum	Milk (infant formula)	17	M, S
	Salmonella Java	Milk (toddler)	14	S, D
	Escherichia coli O157	Raw milk	8	D
1998	*Salmonella* Typhimurium	Sold as pasteurized milk	121	M, D
	Escherichia coli O157	Raw milk	3	M
1999	*Escherichia coli* O157	Sold as pasteurized milk	114	S, D
	Escherichia coli O157	Sold as pasteurized milk	11	S,D
2000	*Escherichia coli* O157	Raw milk	4	M
	Escherichia coli O157	Raw milk	2	M

wage benefit. Between 1992 and 2000, only four milk-associated outbreaks occurred in Scotland. All four were associated with drinking raw milk and were restricted to farms and did not involve the general community.

In a recent study of milkborne outbreaks in England and Wales, milk sold as pasteurized was associated with 37 percent of all milkborne outbreaks (Gillespie et al. 2003a). Despite the introduction of a British Standards code of practice for pasteurization of milk on farms and in small dairies (BS7771:1994) and guidelines for 'on farm' milk processors (ADAS 1996) there is a concerning trend of outbreaks associated with milk sold as pasteurized. Most of the outbreaks linked to milk sold as pasteurized in Table 1 were associated with farms and in particular those with on farm dairies. Of the nine outbreaks linked to consumption of milk sold as pasteurized, six were associated with failures of the pasteurization equipment and three with post-pasteurization contamination. In a study in the northwest of England, in which farm-produced pasteurized milk was monitored during a $2\frac{1}{2}$ year period from 1999–2001, 18 percent (24/130) of on-farm dairies produced milk that failed the alkaline phosphatase test (Allen et al. 2004). In the absence of timely control checks and regular maintenance of equipment, farm-bottled milk will continue to be a microbiological safety issue (Gillespie et al. 2003a). The study by Gillespie et al. (2003a) also showed a bimodal seasonality with milkborne outbreaks occurring in spring and autumn which the authors highlight may be due to changing animal husbandry practices.

Evidence from a number of outbreak investigations has shown that it is not uncommon for operators to switch HTST pasteurizers to manual/clean mode during running, thereby removing the safety system and preventing flow diversion. This practice occurs most often with small producers who may be unaware of the exact sequence of events during flow diversion. In dairies that experience pasteurization failures, examination of thermograph records may show that soon after the milk temperature drops, initiating flow diversion, the plant has been switched to manual/clean mode, thus preventing the inevitable delay while the correct temperature is re-established. At the same time this has allowed inadequately heated milk to flow forward (Figures 1 and 2). The Dairy Products (Hygiene) Regulations (HMSO 1995) for England and Wales state that HTST pasteurizers must have an automatic safety device to prevent insufficient heating and an automatic recording device that records operation of the safety system. The regulations for Scotland also state that the record must include a record of when the cleaning mode is in operation. Some of the older designs of farm pasteurizers do not always incorporate chart recorders, which include a record of the operation of the safety system.

Information from some of the recent outbreaks associated with milk sold as pasteurized confirms that there

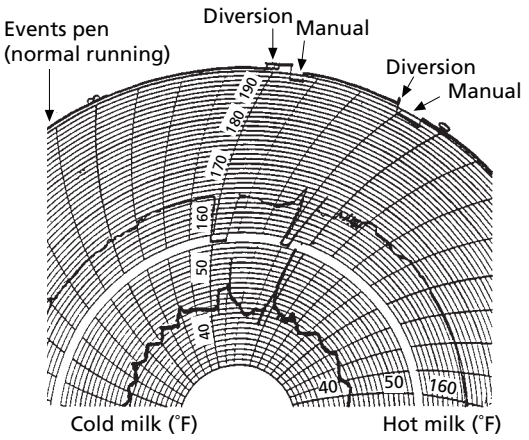

Figure 2 *Part of a pasteurizer thermograph chart demonstrating inappropriate use of manual/clean mode following flow diversion*

are common faults. Integrity of heat exchange plates, problems with flow restriction valves, and incorrect repair of equipment by untrained operatives have contributed to these phosphatase failures. Poor design of dairy plants and addition of other equipment such as homogenizers and cream separators can also alter the efficacy of pasteurization units.

Process control in both large and small plants must include the whole plant. The hygiene of pipes, tanks, bottle or carton fillers, and bottle washers should be monitored and the water supply must be of potable quality. Most dairies use mains tap water but occasionally the supply comes from another source. Whatever the source, water should be sampled regularly to check the microbiological quality. Where bottles are used, the final rinse consists of cold tap water and the bottles are not dried before filling with milk. This could potentially cause recontamination of milk and such a problem occurred many years ago when an outbreak of *Salmonella* Paratyphi B infections that continued for 2 years was eventually traced to river water supplying a pasteurization plant in south Wales (Thomas et al. 1948).

MICROBIOLOGICAL INVESTIGATION OF OUTBREAKS ASSOCIATED WITH ON-FARM DAIRIES

As explained above, most of the outbreaks in England and Wales associated with milk sold as pasteurized are linked to on-farm dairies. Microbiological investigation of these farms is essential to establish the etiology and source of the infecting organism. Microbiological examination should be carried out in conjunction with an evaluation of the process, equipment, and structure of the dairy. Each on-farm producer will have slightly different systems and equipment and therefore each investigation will be different. The microbiological investigations require a team approach and must involve environmental health officers (responsible for licensing

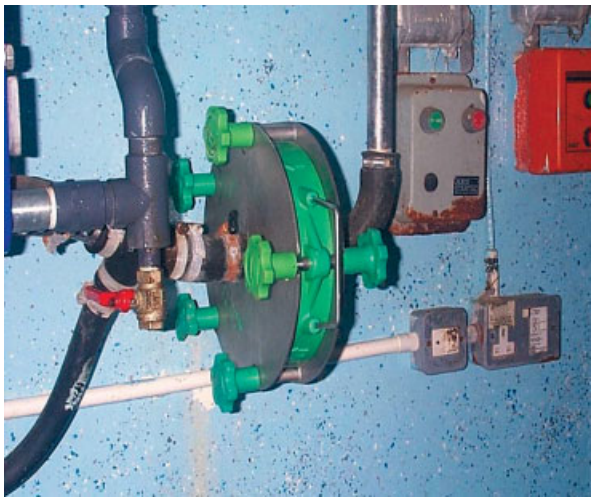

Figure 3 *In-line milk filters sampled during milkborne outbreaks.*

the premises), public health microbiologists, and veterinary microbiologists. The key areas to address are:

- Ensure that the pasteurization and other equipment is functioning correctly and take samples for statutory tests to confirm this.
- Take milk samples for pathogen examination from all pasteurization units, from the bulk milk tank.
- Collect filters or washings from the in-line filter between the milking parlor and the bulk tank (Figure 3). The latter is very important because it is a natural concentration step and will frequently result in isolation of pathogens when other samples are negative.
- Take swabs of any equipment and valve joints that appear to be faulty.
- Environmental samples or swabs from the milking parlor, the processing area and milk bottle/container storage area. Bottle rinses may also be valuable in determining post-pasteurization contamination. Specific sample points can only be decided when visiting the premises.
- Other samples that should be taken from around the farm may include the water supply, water from drinking troughs, samples of soiled bedding, and samples from the midden.
- It may also be necessary to ask a veterinary microbiologist to collect fecal or rectal swab specimens from individual cows. It is important not to limit this to only those cows that are being milked. For example, calves may be the source of the pathogen on an incriminated farm.

SALMONELLA OUTBREAKS

Cattle are the main reservoir of *Salmonella* Typhimurium and it is not surprising that this and other salmonella serotypes are frequently present in raw milk (Threlfall et al. 1980). In the UK study of bottled raw milk, 0.5 percent of samples were salmonella positive and isolates included *Salmonella* Typhimurium phage type DT104, *Salmonella* Dublin, *Salmonella* Virchow PT26, *Salmonella* Anatum, *Salmonella* Havana, and *Salmonella* Ruiru (de Louvois and Rampling 1998). This diversity of serotypes is not unexpected and in a study of 131 dairy herds in the USA Salmonella of O serogroups B, C, D, and E were detected in 6.1 percent of bulk tank milk samples (Jayarao and Henning 2001). These studies confirm that raw milk will from time to time be contaminated with *Salmonella* spp. and will result in outbreaks of infection. *Salmonella* Typhimurium DT104 is now established as a multiresistant clone, although there are subtle differences amongst strains (Threlfall et al. 1997).

During the period from 1992 to 2000, *Salmonella* Typhimurium has been the predominant cause of salmonella associated milkborne outbreaks (Table 1). The growing trend is for these outbreaks to be associated with multiresistant strains of *Salmonella* Typhimurium DT104. Of the nine salmonella outbreaks associated with liquid milk, six were associated with multiresistant *Salmonella* Typhimurium DT104. A large outbreak in 1998 that affected 121 cases was caused by a ciprofloxacin-resistant multiresistant strain of *Salmonella* Typhimurium phage type DT104. There was evidence from molecular typing that this strain developed ciprofloxacin resistance following treatment of cattle in the herd with enrofloxin a few months prior to the outbreak (Walker et al. 2000).

However, large processing dairies produce thousands of gallons of pasteurized milk daily and have the potential for causing major outbreaks if there is an unrecognized fault in the structure or operation of the plant. In 1985 such an outbreak occurred in Illinois, resulting in more than 16 000 confirmed cases of *Salmonella* Typhimurium infection (Ryan et al. 1987; Report 1985).

Salmonella Typhimurium has recently caused a multistate outbreak in the USA (MMWR 2003). Sixty-two cases were linked to consumption of raw milk from a combination dairy–restaurant in Ohio during November 2002 and January 2003. Cases were identified in four states by searching for isolates with a specific pulsed field gel electrophoresis (PFGE) profile. The dairy was the only place in Ohio that sold raw milk in jugs and served raw milk and milk shakes made from raw milk to customers. *Salmonella* Typhimurium with the same PFGE type was also isolated from raw skim milk, butter made with raw milk, and cream. The sale of raw milk is permitted in 27 of the US states and this outbreak has prompted a recommendation that the retail milk regulations should be reviewed and strengthened to minimize the risk from consumption of raw milk.

During the investigation of the multistate outbreak described above, 16/211 workers at the dairy were found to be positive for the outbreak strain. This illustrates the difficulty in determining the role of food handlers in

such outbreaks. There is still no evidence that any milk-associated outbreak was due to asymptomatic carriage of a salmonella by a person. Both the dairy industry and those responsible for enforcing standards should concentrate attention on process control, particularly of pasteurization, instead of screening staff to detect harmless asymptomatic excreters of salmonellae (Editorial 1987).

For further information on salmonella infections, see Salmonella.

CAMPYLOBACTER

Fecal carriage of campylobacters is common in cattle and frequently results in contamination of milk. Typing of isolates from cows within a herd usually reveals that several strains are endemic on the farm and individual cows may excrete one or more strains intermittently. Thus, contamination of milk will reflect the strains circulating within each dairy herd. Several surveys have investigated the prevalence of campylobacters in milk from individual cows, farm bulk tanks, and bottled unpasteurized milk. Between 4.5 and 12.3 percent of untreated milk samples from either bulk tanks or from bottled milk have been shown to be contaminated (Beumer et al. 1988; Humphrey and Hart 1988; Rohrbach et al. 1992). This range of results reflects differences in study design, the volume of milk examined, the sensitivity of the method employed, and on seasonal variations. The most recent microbiological studies of the prevalence of *C. jejuni* in untreated milk report contamination of 2 percent (19/1097) of bottled milk in England and Wales (de Louvois and Rampling 1998) and 9.2 percent (12/131) of bulk milk samples in an American study (Jayarao and Henning 2001). The risk of infection following consumption of unpasteurized milk is substantial and milk has been responsible for large numbers of outbreaks of campylobacter infection in many parts of the world (Skirrow 1991). Robinson (1981) demonstrated on himself that as few as 500 organisms mixed with 180 ml of pasteurized milk were sufficient to induce abdominal cramps, diarrhea, and an antibody response. Thus, a low degree of contamination in a batch of milk could cause a large outbreak. Although *C. jejuni* does not multiply in milk, many strains survive for long periods and can be recovered from milk that has been stored for 14–21 days at 4°C. Pasteurization destroys even large numbers of organisms (Waterman 1982; D'Aoust et al. 1988) and properly controlled heat treatment is the most satisfactory way of ensuring that milk is free from campylobacters.

Most milkborne outbreaks of campylobacter infection reported in the literature have been due to unpasteurized milk (Wood et al. 1992; Morgan et al. 1994b; Orr et al. 1995; Hutchinson et al. 1985b) and the outbreaks listed in Table 1 confirm that in England and Wales from 1992–2000 this is still the case. The outbreaks shown in Table 1 from 1992–1995 have been reviewed by Djuretic et al. (1997) and Peabody et al. (1997) and those from 1996–2000 by Gillespie et al. (2003a). Although the last *C. jejuni* outbreak in England and Wales was reported in 1996, there is evidence from other countries of the continuing risk associated with drinking unpasteurised milk (Kalman et al. 2000; MMWR 2003). Although most milkborne outbreaks are usually caused by a single strain, more than one serotype may be incriminated in a single outbreak. This should not be unexpected if fecal contamination is the source of the organism in the milk.

Another important risk factor for campylobacter infection is consumption of unpasteurized milk during visits to farms for educational, agricultural, or recreational purposes. Wood et al. (1992) identified 20 outbreaks of campylobacter infection amongst children who had consumed raw milk during school field trips and organized youth activities. This mode of transmission is still a problem as highlighted by a recent outbreak in the Netherlands (van den Brandhof et al. 2003). Fifty-seven of 92 children and three teachers drank raw milk provided during the visit to the farm. Forty-seven percent of the 57 children that drank milk developed diarrhea or vomiting and other symptoms. There was a clear dose–response relationship; 17 percent of children that took a mouthful of milk became ill whereas 100 percent of children that drank two cups of milk were ill. In this outbreak, isolates were typed by amplified fragment length polymorphism (AFLP) and they all showed the same pattern. The authors recommend heat treatment of all milk provided during farm visits. Kalman et al. (2000) reported an outbreak in 1998 in Hungary during which they identified 34 confirmed cases of campylobacter infection amongst 500–600 visitors to a farm sale. Similarly, Morgan et al. (1994b) reported the investigation of an outbreak of campylobacter infections in 1992. At a large music festival in southwest England, two local farms had been issued with Temporary Producers Licenses to enable them to sell raw milk at the festival and pasteurized milk was also available for sale. A case–control study based on 72 people with microbiologically confirmed *C. jejuni* infection found that only the consumption of unpasteurized milk was shown to be associated with campylobacter infection. Despite recommendations about the sale of unpasteurized milk, there was another outbreak at the festival the following year that resulted in 22 members of staff being infected (Peabody et al. 1997). Fortunately, on this occasion, unpasteurized milk was not sold to the general public. Campylobacter isolates from cases and the farms collected during both outbreaks were typed by several methods and shown to be indistinguishable. This confirms the endemic nature of pathogenic *C. jejuni* strains within herds for long periods and the potential problem of fecal contamination of milk. In these outbreaks, the supply of unpasteurized milk

resulted in significant but preventable public health problems. It is strongly recommended that visitors to such events and to open farms do not consume raw milk whilst on the premises.

There is also good evidence that *C. jejuni* may cause clinical or subclinical mastitis resulting in the shedding of large numbers of organisms into the milk (Hudson et al. 1984; Hutchinson et al. 1985b; Orr et al. 1995). Outbreaks of infection have also been associated with the consumption of milk from herds in which one or more animals have asymptomatic campylobacter mastitis. In this situation an outbreak could occur even though dairy hygiene is faultless and the milk achieves the microbiological standards for total plate count and coliforms. It is also more likely that milk will be contaminated with greater numbers of campylobacters and hence that the outbreaks will affect more people.

Outbreaks due to improperly pasteurized milk have also been documented on many occasions. In these circumstances, large numbers of people may be put at risk. In 1979, 2 500 children became ill after drinking free school milk supplied from a single milk processing plant in Luton. The campylobacter could not be isolated from the dairy or from raw milk but epidemiological studies strongly indicated milk as a source (Jones et al. 1981). An outbreak of *C. jejuni* enteritis affecting schoolchildren and staff at a boarding school in Vermont in 1986 was traced to inadequate batch pasteurization of milk. Two serotypes of *C. jejuni* were isolated, from both the patients and the dairy cows (Birkhead and Vogt 1988). During 1987, there were two more outbreaks of campylobacter infection in England and Wales, due to improperly pasteurized milk. More than 100 cases were confirmed by culture and serotyping following consumption of milk from a large dairy in East Anglia (Rampling et al. 1987). Another outbreak in 1987 affected 346 students and staff at a field study center in North Wales. Campylobacters were isolated from raw milk prior to pasteurization (Sockett 1991). In 1992 an outbreak in Northamptonshire affected at least 110 people of whom 41 had confirmed infection with *C. jejuni*. Consumption of pasteurized milk from a single farm dairy was implicated by case–control study (Fahey et al. 1995). In all of these outbreaks there was evidence of faulty processing resulting in phosphatase failures. The factors contributing to these outbreaks were: incorrect use of the bypass system (Jones et al. 1981), a leaking valve and inappropriate use of the plant with the safeguards switched off (Rampling et al. 1987), and an incorrectly wired element resulting in plant that had been malfunctioning for some time (Fahey et al. 1995).

Post-pasteurization contamination with campylobacters can also occur as a result of birds pecking milk delivered to the doorstep. This route of contamination was first observed in the late 1980s when magpies and jackdaws were incriminated. This route of transmission was confirmed microbiologically by Hudson et al. (1990, 1991) and epidemiologically by a case control study in south Wales in 1990 (Southern et al. 1990). A further point source outbreak in Exeter in May 1991 affected 11 children at a day nursery and was attributed to consumption of milk that had been pecked by magpies (Riordan et al. 1993). Evidence was obtained from a case–control study and by isolation of campylobacters from two bottles of milk that had been pecked. The most recent outbreak related to bird-pecked milk occurred in 1995 in a residential school in Gloucestershire, England. A retrospective cohort study showed that drinking pasteurized milk from bottles with damaged tops was associated with illness (Stuart et al. 1997). Bird-pecked milk has been suggested as the cause of many of the sporadic cases of campylobacter infection recorded during the annual spring, early summer rise in infections. The demise of doorstep delivery of milk and the growing trend to purchase milk from supermarkets should have an impact on this route of infection.

Peabody et al. (1997) stated that outbreaks of infection are rare events for such a common pathogen and this may in part be due to our inability to recognize that sporadic cases are linked. Two recent epidemiological studies have addressed this issue. A case–control study in Sweden with 101 cases and 198 controls, found that drinking unpasteurized milk was the major risk factor (OR 3.56, 95 percent CI 1.46–8.94) (Studahl and Andersson 2000). Enhanced surveillance of campylobacter cases in England and Wales was launched in May 2000 and analysis of these data also identified that illness in the community was associated with drinking unpasteurized milk (OR 1.55, 95 percent CI 1.06–2.27) (Gillespie et al. 2003b). These studies confirm that the risk associated with drinking unpasteurized milk is still prevalent. It may also be possible that some of the cases currently defined as sporadic cases are in fact part of local unrecognized outbreaks, a question that has been raised by Gillespie et al. (2003b).

For further information on campylobacter infections, see Campylobacter and arcobacter.

VERO CYTOTOXIN-PRODUCING *ESCHERICHIA COLI*

There are many serogroups of *E. coli* that produce verocytotoxins (also called shiga-like toxins) and the bovine is a major reservoir for these organisms (Clarke et al. 1989; Chapman et al. 1993). Not all serogroups of verocytotoxin producing *E. coli* (VTEC) are pathogenic for man, and hence presence of a VTEC in milk or diary product does not necessarily imply a risk to human health. In the UK and North America, VTEC O157:H7 has emerged as the significant public health problem but on mainland Europe and in Australia, non-O157 serogroups are more problematic.

Raw milk contaminated with VTEC is a potential source of human infection. A study in Germany found that 3.9 percent of 127 samples of raw milk and 2.1

percent of 146 samples of certified milk were positive for VTEC (Klie et al. 1997). *E. coli* O157:H was isolated from one raw milk sample, the other isolates comprised five different serogroups with different combinations of virulence markers. The authors concluded that drinking raw milk would continue to be a potential public health problem. Detection of non-O157 VTEC is problematic due to the lack of specific and sensitive culture methods. However, a French study using a PCR-ELISA assay determined that 21.5 percent of 205 raw milk samples contained non-O157 VTEC (Fach et al. 2001).

Most other studies have concentrated on determining the prevalence of *E. coli* O157 in milk. In England and Wales, *E. coli* O157 was detected in 3/1 097 samples of bottled unpasteurized milk (de Louvois and Rampling 1998). However, *E. coli* O157 was not detected in a study in Holland of 1 011 bulk milk samples from different dairy herds (Heuvelink et al. 1998) and in a more recent study in Scotland from 500 samples of raw milk (Coia et al. 2001). Contamination of raw milk is therefore a relatively rare event. Verocytotoxin producing *E. coli* have also been associated with coli mastitis in cows (Stephan and Kuhn 1999). These workers found that 2.8 percent (4/145) of cows with coli mastitis were infected with VTEC but none of the isolates were *E. coli* O157. Although many different VTEC are associated with clinical infection in farm animals, especially in calves and pigs, *E. coli* O157:H7 does not seem to cause clinical infection of animals but has been isolated from healthy cattle and dairy calves (Wells et al. 1991; Chapman et al. 1993). A longitudinal study of infection in the dairy commenced in 1993 and showed that although 29 of 130 cows excreted *E. coli* O157 on one or more occasions during the following year, there was no evidence of clinical disease (Report of the Advisory Committee on the Microbiological Safety of Food 1995).

Growth and survival of *E. coli* O157 in unpasteurized and pasteurized milk has been investigated by several groups of workers. Wang et al. (1997) found that *E. coli* O157 did not grow at 5°C in raw milk and that there was a gradual decrease in numbers after storage for 28 days. In this study, growth was observed at 8°C with an increase of about 1–2 $\log_{10}$ CFU/ml after 4 days and at 15°C about 3–5 $\log_{10}$ CFU/ml was noted after 3 days. In pasteurized milk, *E. coli* O157 continued to grow to populations of greater than 8 $\log_{10}$ CFU/ml at day 7. A report from Holland produced similar findings in that *E. coli* O157 was shown to grow in raw milk at 7 and 15°C (Heuvelink et al. 1998). In a later study, Massa et al. (1999) confirmed that growth at 8°C was strain dependent, some strains producing a 2–3 $\log_{10}$ CFU/ml increase during storage for 9–17 days. The recommendations from all these studies are to store milk at (5°C but, more importantly, to ensure that there is effective pasteurization without the risk of post-pasteurization contamination.

Outbreaks of *E. coli* O157 infection associated with raw milk have been reported from several countries but particularly from the USA, Canada, and the UK. In April 1986, there was a large outbreak of colitis in 60 kindergarten children who had visited a dairy farm in southwest Ontario, where they drank unpasteurized milk (Borczyk et al. 1987). Evidence of infection with *E. coli* serotype O157:H7 was demonstrated by isolating the organism or by detecting verocytotoxin in the feces of 43 patients and by isolation of the organisms from the feces of two cows. Martin et al. (1986) investigated two cases of hemolytic uremic syndrome (HUS) in young children. *E. coli* serotype O157:H7 was isolated from a fecal specimen from one child and also from cattle in both dairy herds which supplied the milk. In December 1992, there was a community outbreak in Oregon, USA which was associated with the consumption of raw milk. Eight people were affected and two were hospitalized (Report of the Advisory Committee on the Microbiological Safety of Food 1995). Keene et al. (1997) described a protracted outbreak, affecting 14 people that occurred over a 2-year period in the Portland area of Oregon, USA. These infections may have been reported as sporadic cases but molecular typing using PFGE demonstrated that isolates from cases had the same PFGE profile. The public health message is clear; raw milk can be contaminated intermittently and unpredictably and this can result in infections in the community from a common source that may go unrecognized as part of an outbreak. Enhanced epidemiological and microbiological surveillance are necessary if such cases are to be recognized.

Table 1 illustrates that *E. coli* O157 has emerged as the most common cause of milkborne outbreaks in England and Wales. Outbreaks are, in the main, associated with drinking unpasteurized milk but have also been linked to milk sold as pasteurized (Gillespie et al. 2003a). The first reported outbreak associated with raw milk in the UK occurred in Sheffield in 1993. Eleven cases, mostly children, were affected with *E. coli* O157:H7, phage type (PT)2, VT2, and three developed HUS (Table 1). The organism was also isolated from farmyard slurry, ten of 105 rectal swabs from dairy cattle, and milk from one rectal culture-positive cow at the farm that supplied the milk (Chapman and Wright 1993). In 1996, cases of infection with *E. coli* O157, PT1 in West Yorkshire were associated with the consumption of unpasteurized milk and the organism was isolated from a bottle of milk (Report 1996). Outbreaks associated with raw milk have continued to occur; one in 1997 resulted in eight cases, another in 1998 in three cases, and of two further outbreaks in 2000, one resulted in four cases and the other two cases (Table 1). The outbreak with four cases occurred in the Oldham area of Greater Manchester and was related to consumption of milk supplied by a single farm. Investigations on the farm recovered *E. coli* O157 from the in-line milk filter

and from 67/127 bovines sampled. All strains from human cases, the milk filter, and the cattle were confirmed as *E. coli* O157 PT 21/28 VT 2 with indistinguishable PFGE profiles. Similarly outbreaks associated with raw milk have been reported in Scotland. One outbreak involving three cases occurred in 1999 and another with two cases in 2000 (Task Force on *E.coli* O157 2001).

Of greater concern are the outbreaks in the UK associated with milk sold as pasteurized that have resulted in large numbers of cases. In May 1994, an outbreak of *E. coli* infection involved a pasteurized milk supply in West Lothian, Scotland (Upton and Coia 1994). One hundred people were affected, 69 had infection confirmed by culture, and one was confirmed by serology. Forty-six were under 15 years of age, and of these, 32 were under 5 years. Almost one-third of patients required hospital admission and HUS developed in nine children. Six required dialysis of whom two now have chronic renal failure. One child who did not have HUS died due to perforation of the large bowel. One elderly woman developed thrombotic thrombocytopenic purpura. More than 90 percent of patients had consumed pasteurized milk from the local dairy and at least seven cases resulted from secondary spread within households. Environmental investigation at the dairy and at the farms that supplied the milk yielded isolates of *E. coli* O157 from fecal specimens from cattle, raw milk from the bulk tank at one of the farms, from a pipe that carried milk from the pasteurizer to the bottling machine, and from a discarded bottling machine rubber at the dairy. The isolates from the patients, the farm, and the dairy were indistinguishable from one another by typing. All were *E. coli* O157:H7, PT2, VT2, and displayed identical PFGE profiles.

There have been four outbreaks in England and Wales associated with drinking milk sold as pasteurized, two in 1996 and two in 1999 (Table 1). One of the outbreaks in 1996 occurred in a rural community in the northwest of England (Clark et al. 1997). Of the 12 cases associated with the outbreak, nine were primary cases that had consumed milk from the farm, and three others were symptomless excreters. Three children <5 years old and one adult were admitted to hospital and one child developed HUS. Investigation at the farm highlighted that a flow restriction valve was faulty on one of the pasteurizers and allowed milk to pass through the heating coil too quickly resulting in inadequate pasteurization of milk. *E coli* O157 was isolated from the in-line milk filter and from two of the cows in the herd. All of the isolates were the same phage type but the isolates from the filter and the cattle had a slightly different PFGE profile than the isolates from the human cases. Distribution of milk from the farm was discontinued and the faulty pasteurization unit repaired. This action prevented further cases. Although no conclusive evidence of the origin of the outbreak was found, the farm was the most likely source. This outbreak highlights the importance of taking preventative action quickly on the basis of good descriptive epidemiological evidence.

The largest milkborne outbreak of O157 infection in the UK occurred in north Cumbria in March 1999 and was associated with drinking milk sold as pasteurized from a local farm dairy (Goh et al. 2002). A total of 114 cases were reported to the outbreak control team and 88 of these were confirmed microbiologically. Twenty-eight (32 percent) of the confirmed cases were admitted to hospital including three children with HUS. A case control study found that illness was strongly associated with drinking pasteurized milk from a local farm dairy ($p = <0.0001$). Microbiological investigations on the farm yielded isolates from calves and the farm environment of *E. coli* O157 PT 21/28 VT2 with a PFGE profile that was indistinguishable from the human isolates. Investigation of the pasteurization unit revealed that at the time of production of the implicated batch, there had been a fault with the heat exchange plates on the pasteurizer and the flow diversion pen on the chart recorder was also broken and hence during routine operation it would have been difficult to ensure that milk was being pasteurized effectively. These outbreaks associated with pasteurized milk raise issues about the effectiveness of current legislation for the prevention and control of milkborne infections.

These milkborne outbreaks, in addition to outbreaks incriminating yogurt and cheese (see later sections), confirm that raw milk, or inadequately pasteurized milk, is an important source of human infection with *E. coli* O157 in the UK. In the light of this evidence, the Advisory Committee on the Microbiological Safety of Food (Report of the Advisory Committee on the Microbiological Safety of Food, 1995) and the Task Force on *E. coli* O157 (2001) have recommended that the government should reconsider banning all sales of raw cows' milk in England and Wales and that raw cows' cream should be subject to the same regulations as raw cows' milk. They also recommend that the industry ensures that the pasteurization of milk and milk products is carefully controlled and that post-pasteurization contamination is avoided.

There is evidence that other serotypes of VTEC that occasionally cause outbreaks of human illness may be derived from milk. In 1994, four people in Helena, MT, USA developed bloody diarrhea due to *E. coli* O104:H21. Further case finding investigations revealed 11 confirmed and seven suspected patients and a case–control study implicated one specific brand of pasteurized milk as the source of infection (Moore et al. 1995). Recently, Allerberger et al. (2003) reported two cases of HUS in Austrian children caused by verocytotoxin producing *E. coli* O26. Both cases, one an 11-month-old boy and the other a 28-month-old girl, had consumed raw milk from a breakfast buffet at the same hotel.

Investigations at the farm supplying the milk resulted in isolation of *E. coli* O26:H- from a cow that had an indistinguishable PFGE profile from the isolates from the two cases.

Non-O157 VTEC characteristically ferment sorbitol and hence culture methods used to detect *E coli* O157 are not suitable for the detection of other VTEC. It is therefore possible that sporadic cases or even outbreaks due to these organisms may be associated with milk, yet go undetected.

For further information on VTEC, see Escherichia.

BACILLUS CEREUS AND *BACILLUS ANTHRACIS*

Spores of *B. cereus* are common in the farm environment and inevitably contaminate raw milk. The extent of contamination can be controlled by careful washing of the udder and teats prior to milking. Post-pasteurization contamination may also contribute to the numbers of spores, and the organism can grow readily and produce toxin in milk. *B. cereus* is a common cause of sweet curdling and bitty cream but documented cases of food poisoning due to *B. cereus* in milk are rare. However, in 1972, an outbreak of abdominal pain and diarrhea of short duration affected 221 schoolchildren in Romania after drinking contaminated milk. Two incidents documented in 1981 in Denmark involved a boy aged 12 months who drank curdled milk and a baby aged 6 months who developed diarrhea and vomiting after drinking contaminated expressed breast milk (Christiansson 1992).

Milk-transmitted anthrax is more of a theoretical than a real danger but difficulties may arise regarding the action to be taken with milk that has been derived from a dairy herd in which anthrax infection is subsequently diagnosed. The chance that such milk could be contaminated is very remote because anthrax bacilli are not excreted in milk until bacteremia develops. This occurs just prior to death at which stage it is likely that milk secretion will have ceased and, furthermore, the animal would be obviously ill and unsuitable for milking. Experiments have also shown that both spores and vegetative cells of *B. anthracis* (unlike those of *B. cereus*) disappear rapidly in milk (Bowen and Turnbull 1992) and infectivity of *B. anthracis* is low by the oral route.

Advice from the Department of Health (London, UK) (PL/CO(95)3 plus appendix and addendum) is that milk from animals known or suspected of being infected with anthrax at the time of milking must be excluded from the rest of the milk supply and sterilized (Anthrax Order 1991). The rest of the milk from the herd or flock must be pasteurized before being offered for sale. Where milk has already entered the public supply or where there is a suspicion that bulk milk may contain milk from an animal that could be suffering from anthrax or has died from the disease, pasteurization should suffice to protect the consumer against the risk of anthrax after consuming the milk.

CORYNEBACTERIUM ULCERANS

Although *C. ulcerans* usually causes only a mild sore throat, it can cause an illness indistinguishable from classic diphtheria. The organism is culturally similar to *Corynebacterium diphtheriae* var. *gravis* but is identified by the production of urease and of the exotoxins of both *C. diphtheriae* and *Corynebacterium ovis*. Cattle seem to be the main reservoir of infection and occasionally excrete the organism in milk. Isolated cases of human infection, including one of classic diphtheria, were identified by Meers (1979) in Devon and Cornwall. He postulated that some of the outbreaks of milkborne diphtheria, which at one time were common in Britain, may have been caused by *C. ulcerans*. Hart (1984) isolated *C. ulcerans* from a patient with a sore throat and from one symptomless carrier, both of whom lived in a farming community. Of the 30 cattle on the farm, eight were excreting toxigenic *C. ulcerans*. Hart also surveyed 52 other dairy herds in north Devon and found toxigenic *C. ulcerans* in milk from four of the herds. The organism does not seem to be prevalent in cattle in the UK nowadays and there have been no new reports of infection associated with milk.

CRYPTOSPORIDIOSIS

An outbreak of acute gastroenteritis due to cryptosporidiosis occurred amongst children at a primary school in Yorkshire in September 1995. There were 52 cases of whom 50 were pupils at the school and two were secondary cases. Initially, water was suspected as the likely source of infection but a case–control study implicated school milk supplied by a small producer with an on-farm pasteurizer. Subsequent investigation at the farm revealed that the pasteurizer had been failing intermittently and had not been working properly at the time of the outbreak (Gelletlie et al. 1997). Cryptosporidia are killed by effective pasteurization and hence this is an important critical control point.

LISTERIA MONOCYTOGENES

The first conclusive evidence that listeriosis was acquired from food was reported by Schlech et al. (1983). Since then it has become clear that many foods, including milk and, in particular, soft cheese, may be contaminated with *L. monocytogenes* and may occasionally cause outbreaks or sporadic cases of human listeriosis (McLauchlin 1993).

L. monocytogenes is prevalent in farm environments, in the feces of cattle, and in raw milk (Slade et al. 1989; Rampling et al. 1992; Sanaa et al. 1993; Fenlon et al. 1995). In addition, the organism survives well in moist environments and multiplies slowly at refrigerator

temperatures. Although it is killed by pasteurization, there may be opportunity for post-process contamination from plant or machinery. Food manufacturers, including manufacturers of dairy products, are very much aware of the problems of *L. monocytogenes* and are now very active in carrying out surveillance for this organism in environments and products.

Samples of milk from farm bulk tanks have shown that a high proportion (up to 16 percent) may be contaminated with *L. monocytogenes* at any one time. However, contamination is usually sporadic and persistent contamination seems to be rare. It can result from fecal contamination or from direct shedding by a cow with subclinical mastitis (Slade et al. 1989; Fenlon et al. 1995). Sanaa et al. (1993) carried out a detailed study of 128 selected dairy farms to assess the risk factors for contamination of milk with *L. monocytogenes*. They confirmed the findings of previous studies that poor quality silage (pH >4.0) was a major risk factor. Other predisposing conditions were infrequent cleaning of the cattle exercise area, obvious fecal soiling of udders, thighs, and anal regions, insufficient lighting in milking barns or parlors, which presumably made it difficult to ensure optimal hygiene during milking, and inadequate disinfection of udder cloths between milkings.

Most of the isolates found in surveys of raw milk belong to serovar 1. More detailed subtyping by multienzyme electrophoresis (MEE) has indicated that many isolates belong to subtypes that are unique to milk or to the environment and are not associated with human or animal disease. However, Fenlon et al. (1995) showed that whereas isolates from 25 of 160 milk producers could be subgrouped into nine different electrophoresis types, most of which were unique to milk, some isolates belonged to a type that had been associated with human infection.

In most instances, liquid milk is probably the original source of *L. monocytogenes* in a dairy product but the environment of dairy plants may also provide a reservoir of contamination from milk and other sources (Cotton and White 1992; Jacquet et al. 1993; Peeler and Bunning 1994). In particular, processing plants that are adjacent to dairy farms are more likely to be contaminated with *Listeria* spp. than processing plants without on-site dairy farms (Pritchard et al. 1994).

The first evidence to suggest that raw milk could be a source of human infection came from Halle in Germany where Reiss et al. (1951) described a pathological condition of stillborn infants which they called *granulomatosis infantiseptica* on account of the distinctive focal necrosis found throughout the bodies. A series of outbreaks of this condition occurred over a long period from 1949 to 1957. Initially, the organism responsible was identified as a new species of *Corynebacterium* but was later recognized as *L. monocytogenes*. These outbreaks were considered to be due to the ingestion of unpasteurized milk (Seeliger 1961).

In 1983, pasteurized milk was implicated in an outbreak in the USA: 49 patients were admitted to hospital in Massachusetts with meningitis, septicemia, or abortion due to *L. monocytogenes* serotype 4b (Fleming et al. 1985). Case–control studies demonstrated that infection was associated with consumption of a specific brand of whole or semi-skimmed pasteurized milk; there had been an outbreak of encephalitis due to *L. monocytogenes* in one of the herds that supplied milk to the dairy. There was, however, no evidence of failure of pasteurization.

Luchansky (1995) reported an investigation in Wisconsin in 1994 which followed recall of four dairy products due to detection of contamination with *L. monocytogenes*. One of these products was a 1 percent low fat chocolate milk which had been stored at inappropriate temperatures and contained 10^9 cfu/ml of serovar 1/2b. It had been implicated in a small outbreak of fever and gastroenteritis in a group of picnickers. The Wisconsin Division of Health then identified four patients retrospectively who had suffered typical invasive listeriosis and had also drunk the recalled chocolate milk.

MYCOBACTERIUM PARATUBERCULOSIS

Mycobacterium paratuberculosis commonly infects dairy cattle, leading to Johne's disease, also known as paratuberculosis, a chronic enteritis in cattle (Collins 1997). *M. paratuberculosis* has been suggested as a possible cause of Crohn's disease in humans but the etiology of Crohn's disease has not yet been established. The association with *M. paratuberculosis* has created significant debate in the last 5–10 years. There is evidence both for and against this theory (Chiodini 1989; Thompson 1994). One of the more convincing cases was reported by Hermon-Taylor et al. (1998). A young boy diagnosed with *M. paratuberculosis* cervical lymphadenitis developed terminal ileitis similar to Crohn's disease 5 years later. The organism was detected by polymerase chain reaction (PCR) in biopsies from both the lymph gland and the inflamed intestine. The infection was treated with a combination of rifabutin and clarithromycin. The debate continues and currently there is no substantial evidence to prove or disprove that infection with *M. paratuberculosis* is a major cause of Crohn's disease (European Commission 2000; Rubery 2001). The possible association with Crohn's disease has also raised the issue that this may be a foodborne disease transmitted in the milk of infected cows. This hypothesis has generated great interest in the organism, its prevalence in dairy herds and milk, and the organism's susceptibility to pasteurization.

Prevalence of *M. paratuberculosis* in dairy herds in Alberta, Canada has been investigated by Sorensen et al. (2003). These workers tested 50 herds for the presence of the organisms by fecal culture and a serum enzyme

immunoassay (EIA). A total of 1 500 cattle from the 50 herds was studied, individual sera were tested by the EIA but fecal samples were pooled so that 500 pooled samples were examined. The true herd prevalence, determined by EIA, was 26.8 percent and that determined by fecal culture ranged from 27.6 to 57.1 percent depending on the number of individual samples positive in each pooled sample.

Grant et al. (2002a) reported the incidence of *M. paratuberculosis* in bulk raw milk and commercially pasteurized cows' milk in the UK. Samples were collected over a 17-month period from March 1999 to July 2000 from 241 approved dairy processing establishments. *M. paratuberculosis* was detected by an immunomagnetic PCR method and a culture method. *M. paratuberculosis* was detected by the PCR assay in 19/244 (7.8 percent) raw milk samples from bulk tanks and in 67/567 (11.8 percent) of pasteurized milk samples. The culture method detected confirmed *M. paratuberculosis* isolates from 4/244 (1.6 percent) of the raw milk samples and 10/567 (1.8 percent) of the pasteurized milk samples. Finding *M. paratuberculosis* in pasteurized milk raises the issue of heat resistance of the organism and its survival after pasteurization.

The effect of pasteurization temperatures and holding times has been the subject of several studies (Grant et al. 1999; Grant et al. 2002b; Lund et al. 2002). Grant et al. 1999 conducted experiments with raw cows' milk spiked with 10^6 CFU/ml of *M. paratuberculosis*. These workers investigated heat treatments ranging from 72 to 90°C for 15 s and also 72°C for 20 and 25 s. Although all treatments achieved a 5–6 $\log_{10}$ reduction small numbers of the organisms (4–16 CFU/10 ml) survived even when heated at 90°C for 15 s. A longer holding time of 25 s at 72°C was more effective and it was concluded that this is more likely to achieve complete inactivation of *M. paratuberculosis* than a higher temperature. In a follow-up study using a commercial-scale HTST pasteurization unit, Grant et al. (2002b) concluded that *M. paratuberculosis* in naturally contaminated milk are capable of surviving commercial HTST pasteurization. Lund et al. (2002) reviewed data from eight studies on the effect of heat treatment of *M. paratuberculosis*. There was significant variation in the strains, culture medium, and methods used which probably explains the differences in the results obtained. These authors highlighted the need for a set of defined performance criteria for pasteurization of milk in relation to *M. paratuberculosis*. Furthermore, information about the heat resistance of this bacterium will enable a decision to be made on the process criterion that is necessary to eliminate the organism in commercially pasteurized milk.

STREPTOBACILLUS MONILIFORMIS

This organism causes a febrile septicemic illness in man, characterized by an erythematous rash, most prominent on the hands and feet, arthralgia, and sore throat. The disease was first described in Haverhill, Massachusetts, where an explosive outbreak affected 86 people and was termed erythema arthriticum epidemicum (EAE). The outbreak was due to consumption of contaminated raw milk (Place and Sutton 1934). In February 1983 an outbreak of EAE affected 130 children attending a boarding school in Chelmsford, Essex. *S. moniliformis* was isolated from the blood of four of the children and unpasteurized milk from a local farm was again the suspected source of infection (Shanson et al. 1983).

STREPTOCOCCUS ZOOEPIDEMICUS

S. zooepidemicus is an animal pathogen commonly associated with infection in horses but occasionally causing clinical or inapparent mastitis in cows. It has been associated with severe milkborne illness in man. In 1968, there was an outbreak of infection among 74 adults and 11 children in a town in Romania, causing sore throat, fever, and lymphadenitis, complicated by post-streptococcal glomerulonephritis in one-third of patients. Consumption of improperly pasteurized milk was implicated and *S. zooepidemicus* was isolated from cows with mastitis (Duca et al. 1969). In one week, three unrelated patients presented to the General Infirmary, Leeds, with *S. zooepidemicus* bacteremia. One patient had meningitis, two had endocarditis, and one subsequently died (Ghoneim and Cooke 1980). Investigations eventually confirmed that unpasteurized milk had been the source of infection in all three cases. In 1983, *S. zooepidemicus* infection was again associated with acute glomerulonephritis in three members of a North Yorkshire family who drank unpasteurized milk from their own cows (Barnham et al. 1983).

The most severe milk-associated outbreak of streptococcal infection in Britain was in West Yorkshire in 1984 (Edwards et al. 1988); 12 people developed *S. zooepidemicus* septicemia or meningitis, and eight died following consumption of raw milk from a single supplier. Three cows in the herd were excreting the organism in the milk. In Australia, a man developed septicemia and glomerulonephritis due to *S. zooepidemicus* and two other members of the family were found to be asymptomatic throat carriers. The source of infection was unpasteurized milk from the house cow and typing demonstrated that the isolates from the three individuals and the cow's milk were indistinguishable from one another (Francis et al. 1993).

In England in 1994, an elderly couple who owned a dairy farm became ill and were admitted to hospital within days of one another (Report 1994c). The man developed fatal meningitis and *S. zooepidemicus* was isolated from his cerebrospinal fluid (CSF). His wife had septic arthritis and the organism was isolated from pus from a knee joint aspirate. Another man who drank milk purchased at the farm gate became ill with

empyema and subsequently died, and a man who had eaten a chocolate cake made with cream from the farm developed endocarditis. *S. zooepidemicus* was also isolated from milk from the bulk tank and from one cow that appeared to have subclinical mastitis. Ribotyping of the isolates from the patients and the milk demonstrated that they were indistinguishable from one another (Burden, personal communication 1995). There have been no further reports in the literature of infections associated with milk in the UK.

It is clear that *S. zooepidemicus* is a rare but extremely serious cause of human illness. When it is diagnosed, milk should be suspected as the source of infection.

For further information on streptococci, see Streptococcus and lactobacillus.

YERSINIA ENTEROCOLITICA

The reported isolation rates of *Y. enterocolitica* from samples of raw milk vary from 14.3 to 48.1 percent. Most strains have the biochemical characteristics of environmental, nonpathogenic strains and are nontypable or belong to serotypes not associated with human illness. A few isolates from milk are pathogenic, however, and yersinia infection has been associated with consumption of raw milk in England and Wales and in the USA.

Y. enterocolitica can survive and replicate at refrigeration temperatures but although one strain of yersinia able to survive laboratory pasteurization has been reported, there is good evidence that HTST pasteurization will destroy all viable organisms (Francis et al. 1980). The presence of pathogenic yersiniae in pasteurized milk implies a fault during pasteurization or contamination afterwards (D'Aoust et al. 1988; Greenwood et al. 1990).

An outbreak in 1976 (Black et al. 1978) resulted in admission to hospital of 36 schoolchildren, 16 of whom had appendectomies. Evidence from a case–control study implicated chocolate milk but chocolate syrup was added to the milk after pasteurization and this may also have been a source of the organism. Case–control studies implicated pasteurized milk in a large multistate outbreak of yersiniosis in the USA in 1982 (Tacket et al. 1984); 172 infections were identified by culture. Enteritis occurred in 148 patients, mostly children, and extraintestinal infection in 24 adults. Appendectomy was performed on 17 patients with intestinal infection. Investigations did not reveal any fault in the pasteurization process but indirect evidence that milk was the source was obtained by isolating the same unusual serotype (O:13,18) from the outside of a milk crate on a pig farm where outdated milk was used as pig feed.

The most recent outbreak associated with *Y. enterocolitica* was reported in the USA (Ackers et al. 2000). Ten patients were infected with *Y. enteroocolitica* O:8, three patients were admitted to hospital and one underwent an appendicectomy. Consumption of pasteurized milk from a local dairy was associated with the illness. Post-pasteurization contamination was the most likely source of the problem originating from either the farm environment, one sample from a pig on the farm was positive, or from contaminated water used to rinse the milk bottles.

MILK POWDER

Commercial drying of milk was introduced at the beginning of the twentieth century. The roller method was developed first followed by the spray method in the 1930s. Both were in operation until the 1950s when the spray method assumed popularity because it gave a more palatable product. For a detailed account of the various processes and designs of plant see Knipschildt and Anderson (1994).

The process is in two stages: preliminary concentration during which 90 percent of the water is removed by evaporation, followed by rapid drying. Before concentration, the milk must be preheated to pasteurization temperatures to kill vegetative pathogenic bacteria. For the spray-drying process, concentrated milk is fed from vacuum evaporators to a balance tank and then through fine jets or rotary atomizers into the top of a large chamber supplied with filtered hot air. Dry powder is collected from the bottom of the chamber.

The development of processing conditions that minimize nutrient change and improve physical and organoleptic properties has increased the microbiological hazards (Lovell 1990). Spray-dried milk has been responsible for many outbreaks of food poisoning due to enterotoxigenic *S. aureus* and to salmonellae. The safety of the process relies on adequate preheating to destroy vegetative pathogenic organisms; if, however, they survive this stage, there is opportunity for them to multiply in the evaporators and the balance tank and thus for heavily contaminated milk to enter the spray-drier. Although hot air enters the spray-drier at over 160°C, cooling is rapid. There is good evidence that salmonellae can survive the drying process (McDonough and Hargrove 1968) and that the heat treatment is insufficient to inactivate *S. aureus* or its enterotoxin. Because of the complexity of the plant, it is very difficult, if not impossible, to eradicate contamination once established in the plant or its environment.

In 1953, several outbreaks of staphylococcal food poisoning in schools near London were traced to powdered milk from the same source. Later that year, another outbreak in Yorkshire was traced to milk powder from a different source (Anderson and Stone 1955). Tests on batches of milk powder from the plant involved in the first outbreak demonstrated that on two days during May the total bacterial concentration was considerably higher than on other days and that there

were approximately 10^4 *S. aureus* per gram. The organism was not detected in batches with low bacterial concentrations. Other studies indicated that toxin was probably produced at some stage before the drying process. Investigations at another plant not implicated in the outbreaks showed that bacteria multiplied in the balance tank throughout the 12 h of continuous processing. There was also evidence that small amounts of contamination remained after cleaning and recontaminated the pasteurized concentrated milk as it passed through the tank (Hobbs 1955). Other studies have indicated that *S. aureus* contamination may occur during manufacture and that isolates from milk powder may not necessarily be the same as those in the raw milk (Lovell 1990). Harvey and Gilmour (1990) examined milk powders from five different processors in Northern Ireland for both *S. aureus* and coagulase-negative staphylococci. They found that low levels of total viable organisms were associated with low total staphylococcal levels but that five of 37 samples had high total levels and high concentrations of coagulase-negative staphylococci. The powders with high levels contained added fat which was mixed into the milk after pasteurization and concentration, but prior to drying. No *S. aureus* or staphylococcal enterotoxins were detected but this study highlighted a potential source of contamination with microorganisms which are able to survive the drying process. Even coagulase-negative staphylococci are undesirable as some strains can produce enterotoxins.

However, staphylococcal intoxication from dried milk does not seem to have caused many problems since the general introduction of refrigerated farm bulk milk tanks, which maintain raw milk at a temperature that inhibits multiplication and toxin production by staphylococci (Morgan-Jones 1987). However, the problem has not totally disappeared. One report from El-Dairouty (1989) describes a series of food poisoning incidents involving 21 patients who consumed non-fat dried milk in Egypt in 1986. The largest outbreak associated with a milk product has recently been reported in Japan (Asao et al. 2003). Over 13 000 cases are likely to have occurred as a result of contaminated powdered milk used as an ingredient in a range of dairy products. Staphylococcal enterotoxin A (SEA) was detected in low fat milk and also in powdered skim milk. The total intake of SEA per capita was estimated at about 20–100 ng. SEA exposed at least twice to pasteurization at 130°C for 2–4 s retained both immunological and biological activity. This outbreak is a reminder that viable *S. aureus* can be eliminated by pasteurization but that the enterotoxin can retain sufficient activity to cause intoxication.

Salmonella infection has been associated with the consumption of powdered milk on several occasions and its occurrence in dried milk is well documented. In 1966, an outbreak of *Salmonella* Newbrunswick infection in the USA was associated with spray-dried milk (Collins et al. 1968). Following this episode, the US Food and Drug Administration instituted a large-scale testing program (Marth 1969) and 156 milk plants in 56 states were examined. Of 2 741 samples tested, 24 samples of non-fat dried milk and 27 environmental samples contained salmonellae. Later, in 1967, 200 factories in 19 states were surveyed: 1 percent of 3 315 product samples and 8.2 percent of 1 475 environmental samples were positive for salmonellae. In total, 13 percent of the plants tested were manufacturing milk powder contaminated with salmonellae. These surveys also demonstrated the value of taking environmental rather than product samples to monitor for pathogenic bacteria.

Outbreaks have continued to occur in the USA. Pickett and Agate (1967) isolated a lactose-positive strain of *Salmonella* Newington from instant non-fat milk powder which had been responsible for nine cases of salmonellosis. *Salmonella* Newport was isolated from dried skimmed milk and from 20 patients with diarrhea and vomiting in Newfoundland (Marth 1969) and an outbreak of *Salmonella* Agona and *Salmonella* Typhimurium infection was traced to powdered milk in Oregon (Furlong et al. 1979).

These episodes in North America are not unique. In England and Wales, *Salmonella* Typhimurium infection has been traced to spray-dried milk on several occasions (Galbraith et al. 1982). In Australia, *Salmonella* Bredeney, harbored in the insulating material of a spray-drier, provided a continuing source of contamination for the milk powder via cracks in the stainless steel lining of the drier (Craven 1978). In Trinidad, approximately 3 000 people, predominantly infants and small children, were infected with *Salmonella* Derby which was traced to contaminated powdered milk produced on the island (Weissman et al. 1977).

In November and December 1985, there was a cluster of *Salmonella* Ealing infections in infants in England and Wales (Rowe et al. 1987). Investigations showed that 76 people, including 48 babies, had been infected and that a smaller cluster of cases had occurred in May, June, and July 1985. Seven of the babies were admitted to hospital and one died. A case–control study implicated dried milk from one manufacturer. *Salmonella* Ealing was isolated from an unopened packet of baby food from the home of a patient and from four other packets from the same batch. Investigations at the factory revealed that the inside of the spray-drier had several minor pinholes and weld cracks and that there was an irregular hole 1×3 cm in the metal lining. Removal of the metal outer casing at the site of the hole showed stained insulation material and a large collection of discolored milk powder. *Salmonella* Ealing was isolated from the insulation material and the milk powder in continuity with the hole, but not from the dry insulation material on the opposite side of the drier. It was thus likely that infected milk had gained access to the insulation material from the inside of the drier

through the hole in the metal lining and had then remained within its wall as a continual source of contamination. *Salmonella* Ealing was also found in the factory vacuum system and in a silo containing waste milk powder and sweepings. Examination of the pasteurizer revealed pinhole defects in the plate heat exchanger which could have been sufficient to allow contamination of the pasteurized milk with raw milk. *Salmonella* Ealing was known to be present in one of the herds that supplied milk to the dairy in April 1985 and the organism may have gained access to the factory at that time.

The many incidents of infection associated with spray-dried milk have caused much concern among manufacturers and public health microbiologists. There has also been controversy about standards for total bacterial levels and their relevance as a method of monitoring quality and the frequency of sampling required. A standard for total concentrations of no more than 5×10^4/g after incubation for three days at 30°C is generally accepted (Lovell 1990) but in practice concentrations of less than 1×10^3/g can be achieved. It is customary to perform quality control tests on each batch of powder before releasing it for sale. As was clearly demonstrated by the surveys in the USA in 1966 and 1967, however, this practice is by no means as sensitive for detecting pathogens as testing the dust and waste powder in the factory environment. An obviously dangerous practice in some milk powder factories is the custom of blending powder with high bacterial levels into powder with low bacterial levels in order to give an apparently satisfactory final product (Rowe et al. 1987).

Mettler (1989) has reviewed the issues raised by the *Salmonella* Ealing and other salmonella incidents. He points out that production of pathogen-free milk powder requires detailed committed attention to good manufacturing practice involving every aspect of the process, including design of equipment, management, staff training and discipline, and control of the environment, including air quality. In addition, sampling programs should be detailed and targeted and include the environment as well as the product; the test methodology should be assessed critically in relation to the detection of pathogens. Regular and thorough crack testing of the spray dryer should also be an essential part of the quality control program. In the long term, it should be possible to design spray-drying chambers that do not have this intrinsic fault and it should be possible to improve the processing equipment at all stages so that a build up of microorganisms does not occur.

An outbreak of *Salmonella* Anatum infection in babies in late 1996 and early 1997 associated with infant dried formula, is a stark reminder of the potential of dried milk products to cause widely dispersed outbreaks. This outbreak was only recognized because of the joint national referral of salmonella isolates to the reference laboratory for typing and the national surveillance system in England and Wales. A case–control study on the first 12 cases strongly associated consumption of infant dried formula. Subsequently, the isolates from the cases were shown to have indistinguishable PFGE profiles. A wider investigation revealed that 22 cases had occurred from September 1996 to January 1997 in four different countries: 13 in England, four in Scotland, four in France, and one in Belgium (Anon 1997). The infant formula was produced at a factory in France and upon further Europe-wide investigation it became apparent that there were also cases in France. Investigation revealed that the spray-dried milk used to make the infant formula may have originated from either a plant in France or the Netherlands. This outbreak illustrates the complexity that has developed in the modern food chain and dairy industry and the essential need for Europe-wide microbiological and epidemiological surveillance.

Although guidelines for the hygienic manufacture of spray-dried milk powders have been issued by the International Dairy Federation (Report 1991a) incidents continue to occur. In 1993, Louie et al. reported that three cases of *Salmonella* Tennessee infection in infants had been traced to the consumption of one particular brand of powdered infant formula and that this organism had also been isolated from production equipment at the spray-drying plant and from cans of powdered milk formula.

Salmonella spp. and *S. aureus* are the pathogens most often associated with dried milk, but other organisms have also caused public health problems. Three cases of neonatal meningitis due to *Enterobacter sakazakii* from infant milk formula were diagnosed in 1986 and 1987 at the National University Hospital, Reykjavik, Iceland (Biering et al. 1989). Two neonates who were normal at birth survived with severe brain damage and a third, who had Down's syndrome, died. *E. sakazakii* was isolated from cerebrospinal fluid from the three babies with meningitis and from the urine of a fourth infant who had no signs of infection. It was also isolated by enrichment culture from five unopened packages of milk powder. All isolates from the babies, and all but one of 23 isolates from the infant formula, had identical biotypes, antibiograms, and plasmid profiles. Other workers have isolated *E. sakazakii* from powdered milk (Muytjens et al. 1988) and powdered infant milk has been suspected in the past as a source of neonatal infection with this organism (Muytjens et al. 1983). These incidents confirm the importance of implementing the strictest possible measures for the control of microbiological quality during the manufacture of milk powder and, in particular, of infant milk. The Reykjavik outbreak demonstrated that even low numbers of *E. sakazakii* were significant perhaps because of the extreme susceptibility of the patients but also possibly because there was opportunity for multiplication in the reconstituted formula.

B. cereus is another contaminant of raw milk that is commonly present in milk powder (Becker et al. 1994; Crielly et al. 1994). The endospores are heat-resistant and able to survive the pasteurization and drying process. Indeed, replication may be encouraged at various stages of the production process and, in the case of infant formula, further contamination may be introduced with added ingredients. Once reconstituted, there is opportunity for germination of spores, growth, and enterotoxin production depending on the temperature of storage. In spite of this, *B. cereus* has rarely been documented as a cause of food poisoning associated with dried milk (Christiansson 1992; Becker et al. 1994). Finally, *C. perfringens* is another sporing organism which is a theoretical risk but has rarely been implicated in food poisoning due to powdered milk (Lovell 1990).

CREAM

Unless hygiene is strict, environmental contamination of cream may be considerable because of the many stages of handling during processing. When cream is separated by centrifugation, most of the bacteria from the whole milk are separated with the cream. In addition, separation is often performed at 40–50°C which is a temperature that encourages the growth of many microorganisms (Milner 1995). However, cream is normally subjected to higher pasteurization temperatures (up to 80°C) than milk and is expected to have a longer shelf-life (Davis and Wilbey 1990).

In 1970, a PHLS working party examined 4 385 heat-treated, 282 clotted, and 517 raw samples of cream (Working Party to the Director of the Public Health Laboratory Service 1971). Bacterial levels were frequently high and, although the unheated creams were the most unsatisfactory, many heat-treated creams also contained large numbers of bacteria including coliforms, thereby indicating either post-pasteurization contamination or inadequate heat treatment. From 3 417 samples examined, *S. aureus* was isolated from 59, 54 of which were unpasteurized. Other pathogens found in untreated samples were one isolation each of *Salmonella* Typhimurium, *B. abortus*, and *E. coli* serotype O126. *C. perfringens* was isolated from one heat-treated sample.

Infections and intoxications associated with cream

Raw cream is as likely as raw milk to contain pathogenic bacteria (Rothwell 1979). It is, however, surprising that few outbreaks have been attributed either to raw or to heat-treated cream. This may be because relatively small volumes are produced and sporadic infections are seldom reported. Furthermore, cream is usually incorporated into desserts, cakes, sauces, etc., and it may be difficult to incriminate the cream alone in the event of an outbreak. Food poisoning due to enterotoxigenic *S. aureus* was a well-recognized hazard associated with cream before the introduction of farm refrigeration tanks and refrigerated storage in shops and homes. When detailed investigations have been made, the source of the organism has usually proved to be a cow or cows with symptomatic or asymptomatic *S. aureus* mastitis. Isolation of the same phage type of *S. aureus* from individual cows, from the cream and from patients with food poisoning has been reported (Steede and Smith 1954).

Raw and pasteurized cream have also been associated with many small incidents of salmonella food poisoning, often related to overt infections in cows or calves on the farms supplying the milk (Vernon and Tillett 1974; Sharp et al. 1985). There have also been incidents of *B. cereus* food poisoning associated with cream (Galbraith et al. 1982; Sockett 1991).

The potential risk associated with the consumption of raw cream was demonstrated in the outbreak of infections with *S. zooepidemicus* which occurred in the home counties of England in 1994. An elderly patient who developed endocarditis due to this organism acquired his infection by eating a chocolate cream cake made with contaminated raw cream (Burden, personal communication 1995). It is probable that he was unaware that the cream was unpasteurized.

Raw cream has also been incriminated as a source of *E. coli* O157. An outbreak in England in 1997 was linked to consumption of raw cream purchased from a farm shop. Descriptive epidemiological evidence indicated that consumption of raw cream from the one outlet was associated with infection in the seven confirmed cases (Task Force on *E. coli* O157 2001).

YOGURT

A wide variety of drinks and semi-solid foods are prepared by the fermentation of milk and yogurt is by far the most popular. Nearly all yogurt is made in large dairies under carefully controlled conditions but there is increasing interest in small-scale farm production, particularly from sheep and goat milks.

There are two systems for commercial manufacture (Robinson and Tamime 1993). In one, incubation and fermentation are performed in the retail container, resulting in *set yogurt*. In the other, fermentation takes place in large tanks and the coagulum is stirred to produce a thick viscous fluid (*stirred yogurt*) which is cooled and packaged by automatic fillers. Fruits or flavorings are added to stirred yogurt after fermentation is completed and to set yogurt before fermentation. Stirred yogurt is sometimes pasteurized to give it an extended shelf-life.

The first stage of manufacture for both products is preparation and standardization of the milk mix. Fresh milk is preheated and separated through a centrifugal

separator. The concentration of total solids in the skimmed milk is increased, either by evaporation to 15–16 percent or by adding milk powder. If a medium or full fat yogurt is required, a monitored amount of cream and sugar is added. Stabilizers, such as pregelatinized starch or plant gums, may also be included at this stage. The mix must be homogenized if cream is added, otherwise separation will occur during incubation. Homogenization also increases the viscosity.

The mix is heat treated to kill pathogenic and spoilage organisms and to expel air in order to produce microaerobic conditions for the fermentation. The optimum heat treatment for improving the physical state of the coagulum is a high temperature, prolonged treatment (85°C for 30 min). This is done in large tanks containing mechanical stirrers and heated by water jackets. The tanks are then cooled to 40–45°C, inoculated with the starter cultures and held at constant temperature until fermentation is complete after $3\frac{1}{2}$–$4\frac{1}{2}$ h. Many dairies find this system too slow and prefer to treat the mix in a UHT pasteurizer (85°C for 2 s) before filling the fermentation tanks or the small volume containers used for set yogurt.

Almost without exception, commercial producers use *Streptococcus thermophilus* and *Lactobacillus bulgaricus* in a ratio of 1:1 as a starter culture for fermenting yogurt. The cultures are grown in milk in bulk starter vats and added to the basic mix to give a final concentration of 1–2 percent (v/v). An incubation temperature of 40–42°C is usually selected for the fermentation. This temperature lies between the optima for acid production by the two species (39°C for *S. thermophilus* and 45°C for *L. bulgaricus*). The two organisms grow symbiotically; *S. thermophilus* produces metabolites that encourage the growth of *L. bulgaricus*. *S. thermophilus* produces most of the lactic acid early in the fermentation, but later, both organisms produce aldehydes and other fermentation products important for flavor. The final acidity is greater if the two cultures are grown together than if either is grown alone. A final concentration of 1 percent lactic acid (pH 4–4.2) should be achieved. Strict quality control is essential to ensure that starters are active and free from bacterial and bacteriophage contamination, and that the milk is free from antibiotics which would inhibit growth of the starter.

Microbiological quality of yogurt

Yogurt mix is heated to very high temperatures before fermentation. It should therefore be free from pathogenic and spoilage organisms but opportunities exist for contamination during fermentation and packaging. Additions such as fruit or flavorings may also carry contaminants. However, it is generally a very safe product because most potential pathogens are inactivated by the high level of acidity and antibiotic substances produced by the starter cultures (Robinson and Tamime 1990). *Campylobacter* spp. and *Salmonella* spp. are inactivated rapidly in yogurt or fermented milks, but under experimental conditions both *Y. enterocolitica* and *L. monocytogenes* can survive for several weeks in the refrigerated product (Schaack and Marth 1988; Ashenafi 1994; Aytac and Ozbas 1994). Between 1988 and 1991, a survey of the occurrence of *Listeria* spp. in milk and dairy products in England and Wales included 180 samples of yogurt. *L. monocytogenes* was isolated from four yogurt samples (one made from cows' milk, two from goats' milk, and one from ewes' milk) (Greenwood et al. 1991). However, yogurt does not seem to have been associated with any cases of human clinical infection due to *L. monocytogenes* or *Y. enterocolitica*.

Provided that yogurt is produced under carefully controlled conditions with the correct starter cultures, pathogenic bacteria, but not their toxins or spores, should die out rapidly. The quality of added ingredients is equally important and these should be subject to the same quality control. An outbreak of staphylococcal food poisoning involving at least 67 people was traced to *dahi* (Indian yogurt) made in a shop in Calcutta (Saha and Ganguli 1957). The suspected source was contaminated milk powder added to the mix just before incubation. It was clear that there was a fault in the fermentation process because it took 36 h to complete. The staphylococcal enterotoxin was presumably produced during this time.

Until 1989 there were no records of outbreaks of human infection associated with yogurt in England or Wales or Europe (Galbraith et al. 1982; Sharp 1987). In June 1989, however, yogurt was associated with the biggest outbreak of botulism in Britain during this century (O'Mahony et al. 1990). Between 30 May and 13 June 1989, 27 cases of botulism, with one death, were traced to the consumption of low fat hazelnut yogurt. *Clostridium botulinum* type B toxin was detected in the contents of an unopened can of the hazelnut purée used to flavor the yogurts, and from unopened cartons of yogurt. The yogurt was made in the northwest of England, and the hazelnut purée was supplied in 6 lb cans by a factory in Folkestone. The hazelnut purée was sweetened with aspartamine, rather than sugar, which might have prevented bacterial growth, and insufficient heat had been used in the manufacturing process to destroy spores of *C. botulinum*.

In the autumn of 1991, an unusual outbreak of *E. coli* O157:H7 PT 49 infections was associated with consumption of a brand of live yogurt made specially for children by a farm producer in the northwest of England (Morgan et al. 1993). Sixteen cases of culture confirmed infection were identified from 1 September to 1 November 1991. Eleven of the children were age 10 years or less and five developed HUS. A formal case–control study confirmed a close association between

consumption of the yogurt and development of *E. coli* O157 infection. However, the organism was not isolated from raw or pasteurized milk on the farm nor from another batch of the implicated brand of yogurt sampled at a later date.

BUTTER

Butter contains approximately 81 percent fat and, under commercial conditions, is prepared from pasteurized cream with or without the addition of starter cultures which increase the acidity and add flavor. Dairy spreads may be defined as products with more than half their ingredients derived from milk. They have a higher water content than butter and low fat spreads contain additional milk proteins which stabilize the product (Wilbey 1994).

Most of the bacteria that are present in raw milk separate with cream and potentially would contaminate butter, so pasteurization is a very important part of the manufacturing process. The physicochemical characteristics of butter appear to inhibit the growth of many microorganisms but it has been shown that under experimental conditions *Salmonella* spp. can grow in butter at room temperature and may survive for long periods at refrigeration temperatures (El-Gazzar and Marth 1992). It has also been demonstrated that *L. monocytogenes* can increase in numbers during refrigerated storage of butter made from contaminated cream and that both *L. monocytogenes* and *Y. enterocolitica* can grow in some refrigerated dairy spreads (Milner 1995).

Spoilage of butter and dairy spreads may occur due to surface growth of *Pseudomonas* spp. or yeasts and molds (Milner 1995). There have been only a few incidents of food poisoning associated with butter and most of these have been due to *S. aureus* enterotoxin. In 1970, 24 customers and staff at a department store in Alabama became ill with acute gastroenteritis soon after consuming whipped butter in the restaurant. The butter had been prepared at the restaurant by whipping milk with softened butter but microbiological tests showed that the butter, not the milk, contained *S. aureus*. The same brand of butter was also implicated in a single case of typical staphylococcal food poisoning in Tennessee a few days later; tests on the butter demonstrated the presence of staphylococcal enterotoxin A (Wolf et al. 1970). A second outbreak of staphylococcal food poisoning, also associated with commercially produced whipped butter, occurred in Kentucky in 1977. More than 100 cases were diagnosed some of whom were admitted to hospital (Francis et al. 1977).

In 1991, an outbreak of food poisoning in California and Nevada involved more than 265 people and was traced to butter blend and margarine that was contaminated with enterotoxin-producing *Staphylococcus intermedius*. Isolates from patients and product produced staphylococcal enterotoxin A and PFGE analysis of restriction enzyme digests of DNA from five clinical and ten food isolates provided evidence that all the isolates were derived from a single strain (Bennett et al. 1994).

Another very serious outbreak of gastroenteritis followed by HUS affected nine children age 1–3 years at a nursery school in Germany (Tschäpe et al. 1995). All nine children required admission to hospital and dialysis and one boy died shortly after the onset of illness. In addition, six children age 4–6 years developed gastroenteritis without HUS. The children had eaten sandwiches prepared with 'green' butter that was made by mixing parsley with the butter. The parsley originated from a garden enriched with pig manure. The organism responsible for the infection was a verocytotoxin producing isolate of *Citrobacter freundii* which was isolated from patients, some symptomless contacts, and from the parsley. The isolates from the patients and the parsley were shown to be toxigenic by specific DNA probes and PCR and to be genetically indistinguishable from one another. This outbreak again demonstrates that the quality and hygiene of added ingredients are as important as those of the dairy product.

ICE CREAM

Ice cream usually contains 8–18 percent fat, 9–12 percent milk solids-not-fat, sugar, small amounts of stabilizer, and emulsifier. If the fat is entirely milk fat the product is known as dairy ice cream. When vegetable oils or other animal fats are used in manufacture the product cannot be described as 'dairy' ice cream.

Ice cream is a complex product and manufacture consists of several stages. Detailed descriptions of the process and plant are given by Rothwell (1990) and Mitten and Neirinckz (1993). Initially, the mix is blended to give a homogenous product. Compositional and heat treatment legislation varies considerably around the world but most countries require pasteurization (Rothwell 1990). Following pasteurization, the mix is homogenized and then cooled to 4°C or below and held in a tank for a variable time ranging from 4 to 12 or more hours to undergo aging. During the aging process, protein is adsorbed to fat globules, fat crystallization occurs, and stabilizers increase in hydration. In large, highly mechanized, and sophisticated ice cream plants, the aging process is carefully controlled and relatively short. However, some processors use a longer aging time of 24 h or more and at this stage there is opportunity for psychrotrophic microorganisms to multiply unless careful attention is paid to hygiene and prevention of post-pasteurization contamination.

Following aging, the mixture is frozen rapidly with agitation and air is incorporated into the mix. It is then extruded and may be dispensed as soft-serve ice cream or packaged into bricks or large containers which are hardened at between −20 and −40°C and sold as hard ice cream. Flavorings are usually added to the mixing or

aging tanks, but pieces of fruit, nuts, syrups, or purées are added to the ice cream after extrusion from the freezer.

Microbiological quality of ice cream

There were many small and large outbreaks of food poisoning due to ice cream in the UK prior to the introduction of heat treatment legislation for commercial ice cream (Rothwell 1990; Nichols and de Louvois 1995). Outbreaks of both *S. aureus* and salmonella food poisoning are recorded. In 1946, a large outbreak of typhoid fever in Aberystwyth in Wales affected more than 100 people with four deaths and was due to contamination of the ice cream by the manufacturer who was a typhoid carrier (Evans 1947). Following this incident, heat treatment regulations were introduced but did not become effective immediately and between 1950 and 1955 there were 19 recorded outbreaks associated with consumption of ice cream and ice lollies (11 due to *Salmonella* spp., two due to *S. aureus*, and six of unknown cause) (Rothwell 1990). Between 1955 and 1984, there were no outbreaks reported in the UK but since 1984 there have been a number due to home-made ice cream. In 1984, an outbreak of *Salmonella* Enteritidis PT4 infection involving 12 people was attributed to home-made ice cream (Barrett 1986). In 1987, six members of a family were ill with *B. cereus* poisoning after eating home-made ice cream containing egg white and fresh cream. The product had $>10^{10}$ *B. cereus* per ml (Sockett 1991).

Several outbreaks of *Salmonella* Enteritidis PT4 infection have occurred due to the use of raw shell eggs in home-made ice cream. In 1988, an outbreak affected 18 of 75 people at a bridge party (Cowden et al. 1989). In 1991 there were three family outbreaks (Report 1991b; Morgan et al. 1994a) and in 1993 another outbreak affected seven staff at a hotel (CDSC 1993, unpublished data). In the UK, it is illegal to use unpasteurized egg in commercial ice cream but it is clear that the continued use of raw egg in domestic homes and by commercial caterers poses a serious threat of food poisoning which may sometimes involve large numbers of people. A large number of outbreaks of salmonellosis in other countries have also been associated with unpasteurized ice cream and the use of contaminated eggs (Nichols and de Louvois 1995). A more recent very large outbreak involving more than 2 000 people in the USA was attributed to the use of eggs in nationally distributed ice cream products (Report 1994d).

Ice cream may also become contaminated with *L. monocytogenes*. In 1986, contamination of ice cream bars in the USA was thought to be responsible for a flu-like illness affecting at least 40 people in four states. This resulted in a recall of the product. Listeria contamination requiring recall of product has also been reported on other occasions in ice cream in the USA and France (Rothwell 1990).

Most countries have strict standards for hygiene and heat treatment requirements for commercial ice cream and it is clear that careful control of both ingredients and the production process is needed to produce a hygienic product and prevent post-pasteurization contamination. In 1992, in the UK, the Ice Cream Federation and the Ice Cream Alliance in collaboration with the Milk Marketing Board produced guidelines for the hygienic manufacture of ice cream and for the safe handling of products by retailers (Report of the Ice Cream Alliance and the Ice Cream Federation 1992a, b). These outline the main principles of quality assurance and attention to premises, raw materials, equipment, and finished products.

A survey of the microbiological quality of 2 612 samples of ice cream, ice lollies, and similar frozen products, was performed in England and Wales in 1993 as part of the European Community Coordinated Food Control Programme (Nichols and de Louvois 1995). The results of this survey demonstrated wide variations in microbiological profile but concluded that, generally, ices were of good quality and unlikely to cause food poisoning. However, nonbranded hard ice creams and soft ice creams were more likely to contain high levels of aerobic bacteria, indicator organisms, and potential pathogens than branded ice cream bars. *L. monocytogenes* was found in four of 1 964 samples of nonbranded hard ice cream and soft ice cream and *Salmonella* Enteritidis PT4 was isolated from a sample of 'real fruit' ice cream.

CHEESE

Cheeses are a heterogeneous group of foods made by coagulating the solids from high or low fat milk by the action of lactic acid and rennet. The curds so formed are treated with varying degrees of heating ('scalding'), cutting, salting, and pressing to produce greater or less acidity and moisture content. The resulting cheese can vary in size, softness, consistency, and degree of ripening. Further modifications depend on the type of lactic acid bacteria used to initiate souring and on whether other bacteria or molds are encouraged to grow within the cheese or on the surface. Survival of pathogens or development of spoilage organisms depends on the physical and chemical characteristics of the cheese and on the degree of maturation. Cheeses may be classified broadly into three main types: hard and semi-hard pressed cheeses, semi-soft cheeses which are usually not pressed, and soft cheeses. Hard cheeses include Parmesan, Gruyère, Cheddar, Derby, Leicester, Caerphilly, Edam, Gouda, and Fynbo. Soft cheeses include Camembert, Brie, Livarot, Cambazola, Cambridge, and Coulommiers, and semi-soft include Munster, Stilton, Roquefort, Gorgonzola, and Mozzarella. There are also

a few unshaped curd cheeses such as cottage and lactic cheese which have high moisture content and acidity, and a very limited shelf-life (Shaw 1993; Tamine 1993).

Hard cheeses such as Cheddar or Swiss are typically large, with low moisture content (c. 39 percent) and a clear rind. The curds are scalded and then matted together while in the vats, 'milled', or chopped, salted, and pressed into molds under heavy weights. Ripening takes 3–9 months and proceeds evenly throughout the cheese. Flavor depends on enzymes from the starter culture and from rennet. The starter is usually a mixture of subspecies of *Lactococcus lactis*. Swiss cheeses such as Emmenthal and Gruyère are manufactured at high temperatures. Thermoduric starters such as *Streptococcus salivarius* subsp. *thermophilus* or *Lactobacillus* spp. are used. In addition, cultures of propionibacteria are added for development of the essential and characteristic flavors.

Semi-hard cheeses such as Caerphilly, Lancashire, and the Dutch cheeses, are lightly pressed cheeses with a moisture content of around 45–50 percent. The textures vary from smooth to crumbly. Most semi-hard cheeses are matured for 1–3 months, but Caerphilly is usually eaten while quite fresh (around 2 weeks old) and Lancashire may be matured for as long as 12 months.

Soft cheeses have a high moisture content of 55–60 percent. The curds are not cut or scalded but are drained into small molds without pressing. Cheeses such as Coulommiers or Cambridge are eaten fresh within a few days but surface-ripened cheeses such as Camembert or Port Salut are surface-ripened for 1–6 weeks by molds (*Penicillium camemberti*) or bacteria (*Brevibacterium linens*).

Internally mold-ripened cheeses such as Gorgonzola or Stilton are semi-soft cheeses with a moisture content of 45–55 percent. They are made with high acid curd to which either *Penicillium glaucum* or *Penicillium roqueforti* is added. The curd is filled into tall molds, which are turned frequently so that it is pressed down by its own weight. After a few weeks, the cheeses are pierced with skewers to admit air and encourage growth of molds. Ripening is complete after 3–6 months, during which the pH rises to 6.0 or more, and lipolysis and proteolysis contribute to the flavor.

Defects and spoilage of cheese

Cheeses made from unpasteurized milk may develop numerous defects depending on the microbial quality of the raw milk and on subsequent contamination from vats and other equipment, and from the curing rooms in which they are matured. The quality of cheese made with pasteurized milk depends mainly on the extent of contamination during manufacture and storage (Chapman and Sharpe 1990). Off flavors and gas production early in manufacture are usually due to lactose-fermenting Enterobacteriaceae or, sometimes, to lactose-fermenting yeasts. Swiss-type cheeses are liable to develop gas some weeks later due to clostridial contamination. Surface growth of yeasts, molds, or proteolytic bacteria can cause softening or discoloration of the rind and spoilage of the cheese. Blue vein cheeses are particularly susceptible to this defect. Growth of yeasts and molds or slime production by psychrotrophic organisms is common in cottage cheese. Production requires a very high standard of plant hygiene.

FUNGAL TOXINS

Cheese-making experiments show that aflatoxin M_1 in milk will survive pasteurization and the cheese-making process, and will not deteriorate on storage. Growth of toxin-producing molds in cheese is also possible. *Penicillium* spp. can produce toxins such as penicillic acid, patulin, cyclopiazonic acid, and roquefortins both at room temperature and at temperatures below 10°C (Chapman and Sharpe 1990). Toxin-producing strains of *Penicillium* have been isolated from both Cheddar and Swiss cheese. There is concern that some of the strains of *P. camemberti* and *P. roqueforti* used for making blue cheese may be toxigenic, but conditions in the cheese tend to be unfavorable for toxin production because of the low content of carbohydrate. Many countries, however, now screen for and select nontoxigenic strains for cheese production. The development of aflatoxin in cheese is probably of less concern because *Aspergillus flavus* and *Aspergillus parasiticus* do not produce toxins at temperatures below 10°C, at which most hard and semi-hard cheeses are ripened.

BACTERIAL TOXINS

Histamine poisoning associated with the consumption of cheese was first reported by Doeglas et al. in 1967. In 1980, a small outbreak occurred in New Hampshire, USA. Specimens of suspect cheese contained 187 mg of histamine per 100 g and a strain of *Lactobacillus buchneri* isolated from the cheese was found to have very high histidine carboxylase activity (Sumner et al. 1985). Staphylococcal enterotoxin has also been the cause of many outbreaks of food poisoning associated with cheese.

Pathogenic bacteria in cheese

The efficient pasteurization of milk should eliminate the risk from all viable pathogenic organisms but many cheese makers still use raw milk or add raw milk to the cheese milk, believing it to be essential for good flavor. Survival of pathogenic organisms in cheese depends on the method of manufacture, the competitive effect of the lactic acid-producing starter bacteria and on conditions of storage and length of maturation of the finished product. Safety cannot be guaranteed if cheese is made from raw milk.

There have been many outbreaks and sporadic cases of infection or food poisoning, including brucellosis and

botulism, associated with the consumption of cheese. Most detailed investigations have demonstrated that the source of contamination was raw milk, inadequately pasteurized milk, or post-pasteurization contamination with organisms originally derived from raw milk. The most recent botulism outbreak occurred in Italy and was linked to eating a dessert made with mascarpone cream cheese (Aureli et al. 2000). The outbreak was caused by *Clostridium botulinum* type A and affected eight young people, one of whom died, having eaten Tiramisu. Type toxin A was detected in five sera and six stools from the patients and in samples of Tiramisu. The authors postulate that a break in the cold storage of the dessert probably lead to germination of the *Clostridium botulinum* spores and toxin production.

Tuberculosis in man has not been traced directly to the consumption of cheese but experimental work has shown that *M. tuberculosis* can survive in many varieties of cheese.

BRUCELLOSIS

Brucellosis is still an important cause of human and animal infection; 500 000 new cases of human infection are reported annually throughout the world. Many cases are associated with consumption of cheese made with raw milk. It has been shown that *B. abortus* and *B. melitensis* can survive and remain viable for many months even in hard cheese such as Cheddar (Chapman and Sharpe 1990).

Wallach et al. (1994) described an outbreak affecting an Argentine family after eating unpasteurized goats' milk cheese. Nine of 14 became ill with *B. melitensis* and blood cultures were positive from seven patients.

Human brucella infection is rare in England and Wales and, with very few exceptions, is acquired abroad after consumption of raw milk and cheese. Two cases of *B. melitensis* were reported in a family who stayed in Malta in April 1995 and ate a locally produced cheese pastry. They were among those affected in an outbreak involving at least 135 people (one death) which was linked to consumption of a soft cheese made with unpasteurized goats' and ewes' milk (Report 1995).

STREPTOCOCCUS ZOOEPIDEMICUS

In 1983, 16 cases of *S. zooepidemicus* occurred in New Mexico and were traced to a home-made cheese made with raw cows' milk which was sold at several stores. A case–control study confirmed the association between *S. zooepidemicus* infection and eating the suspect cheese. In addition, the organism was isolated from multiple samples of cheese and from milk from the cattle at the farm (Espinosa et al. 1983).

STAPHYLOCOCCUS AUREUS

Cheese is the milk product most often associated with food poisoning due to *S. aureus* enterotoxin. This organism is a common cause of mastitis in cattle and common in raw milk. Toxin may be present before pasteurization if the milk has been stored at ambient temperature. If sufficient numbers of *S. aureus* are present at the start of cheese-making, either because raw milk is used or because of post-pasteurization contamination, they may multiply and produce toxin during the cheese-making process (Minor and Marth 1972). Experiments with cheddar cheese-making have shown that even heavily contaminated milk is unlikely to become toxic if the starter culture is working normally. If, however, development of acidity is slow because of the presence of bacteriophage, the numbers of *S. aureus* may attain values of 10^6–10^8/g and produce toxin in the curd. During ripening, the numbers of *S. aureus* decline over the course of a few days or weeks in normally acidic cheese but may continue to multiply in cheese of low acidity during the first few weeks of ripening and survive for months thereafter.

Between 1951 and 1980, cheese was implicated in 16 recorded outbreaks of *S. aureus* food poisoning involving 507 people in England and Wales (Galbraith et al. 1982). Cheddar, Stilton, home-made soft cheese, and Romanian hard cheese were included. In ten outbreaks it was suspected that contamination occurred during manufacture. In the 1950s and 1960s, *S. aureus* intoxication was the most common cause of food poisoning in the USA, and numerous cases were traced to cheese (Hendricks et al. 1959; Walker et al. 1961). Since the almost universal introduction of refrigerated storage for milk, there have been very few incidents. One small outbreak involving only two people occurred in 1983 (Barrett 1986) and in 1987 cheese was suspected as a source of *S. aureus* intoxication in an outbreak involving 28 of 350 people who attended a buffet lunch of a variety of food items (Communicable Disease Report 1987, unpublished). Sharp (1987), in his survey of infections associated with dairy products in Europe and North America from 1980 to 1985, found no other incidents associated with cheese made from cows' milk. Cheese made from contaminated sheep milk was, however, responsible for outbreaks in France and Scotland.

A series of 36 outbreaks of food poisoning in England from November 1988 to January 1989, affecting 155 people, were linked to consumption of Stilton cheese made from raw cows' milk. Although the microbiology and tests for toxin were negative, the clinical illness was typical of staphylococcal intoxication. Control measures included withdrawal of the implicated cheese from sale and subsequent change to use of pasteurized milk for cheese production (Maguire et al. 1991).

For further information on *S. aureus* food poisoning, see Bacteriology of foods, excluding dairy products and 32, Staphylococcus.

SALMONELLA

Salmonellae can multiply rapidly during the cheese-making process and will survive in the curd unless a high

degree of acidity is reached. During ripening, an initial rapid decline in numbers is followed by a relatively stationary phase. Small numbers have been detected even after storage for 6–10 months at refrigeration temperatures (Medina et al. 1982). It may be difficult to isolate the organisms because small numbers are slow to revive and are not distributed evenly through the cheese. Survival tends to be greater in the middle of the cheese and poor near the surface. The infective dose seems to be low. About 10^4 organisms can cause illness, presumably because the high lipid content of the cheese protects the bacteria from the acidity of the stomach (Ratnam and March 1986). Many outbreaks of salmonellosis have been traced to cheeses of all types. It is clear that effective pasteurization of the milk is the only dependable way of ensuring that salmonellae do not contaminate cheese (Fontaine et al. 1980). From 1980 to 1985, outbreaks were recorded in Italy, Canada, Finland, and Switzerland (Sharp 1987).

In 1984, there was a huge outbreak of infection with *Salmonella* Typhimurium PT10 in the four Atlantic provinces of Canada and in Ontario (Ratnam and March 1986). The outbreak was the largest common source outbreak ever to occur in Canada and involved an estimated 10 000 persons. *Salmonella* Typhimurium PT10 was isolated from the factory-packed contaminated lots of Cheddar cheese as well as leftover cheese recovered from homes of human cases. Estimated numbers of *Salmonella* Typhimurium in the cheese were low but the lots of cheese that were positive also contained high levels of coliforms and *E. coli*. Defective pasteurization was shown to be the underlying cause of contamination and the outbreak strain was isolated from milk from a cow on one of the farms supplying the factory. A careful investigation of the pasteurization process revealed that an employee manually overrode the controller and allowed unpasteurized milk to go through to the vats. The pasteurizer was shut down after filling three vats and later restarted to fill the next three vats so that the first and third vats contained *Salmonella* Typhimurium when contaminated raw milk was being pasteurized (Johnson et al. 1990).

In 1989, an outbreak of *Salmonella* Dublin affected 42 people in England and Wales and was traced to imported Irish soft cheese made with unpasteurized cows' milk. *Salmonella* Dublin was isolated from samples of cheese and from the milk of four cows in the milking herd. The cheese was made on the dairy farm (Maguire et al. 1992).

In 1993, *Salmonella* Paratyphi B infection in south-west France was traced to unpasteurized cheese made from goats' milk. *Salmonella* Paratyphi B was isolated from a batch of cheese and from milk from a goat in a herd that supplied milk to the cheese makers (Desenclos et al. 1996).

The most recent outbreak in the UK occurred in the north of England in late 1996. Nineteen cases of *Salmonella* Goldcoast infection were linked by microbiological and epidemiological investigations to consumption of cheddar cheese (Goh, S.K. personal communication). Although the initial cases were in the north of England, additional cases were later identified in other parts of England. The cheddar cheese, made with pasteurized milk, originated from a large commercial cheese manufacturer in Somerset. Microbiological investigations confirmed that batches of the cheese were contaminated with *Salmonella* Goldcoast. Investigations at the factory highlighted process failures during the production of the infected cheese. Veterinary investigation of the farm supplying milk to the cheese manufacturer detected *Salmonella* Goldcoast in cattle on the farm.

Cheese continues to be a possible source of infection with *Salmonella* as demonstrated by an outbreak associated with the consumption of a Tyrolean cheese in Austria. Sixteen cases of *Salmonella* Oranienburg were linked to consumption of the cheese made on a local Alpine farm (Eurosurveillance 2000).

LISTERIA MONOCYTOGENES

The fairly recent association of *L. monocytogenes* infections with soft cheese may be due to changes in marketing practices for dairy products. In recent years, a wider range of dairy products, including many varieties of continental soft cheese, have become popular in Britain and North America and are available in most supermarkets. Many of these products are imported from the country of origin and all have been stored at refrigeration temperatures for days or weeks. *L. monocytogenes* multiplies at low temperatures and minor contamination may increase significantly during storage. *L. monocytogenes* appears to be common in raw milk and many soft cheeses are made from raw milk or have small amounts of raw milk added to them during manufacture. Post-process contamination with *Listeria* spp. may also occur because of the wide environmental distribution of the organism; it can be prevented by strict attention to hygiene and the prevention of cross-contamination during handling and storage (Marfleet and Blood 1987).

In 1985, 86 cases of *L. monocytogenes* infection were identified in Los Angeles and Orange Counties, California (James et al. 1985); 58 cases were in mother–infant pairs. There were eight neonatal deaths and 13 stillbirths out of a total of 29 deaths. Case–control studies implicated Mexican-style soft cheeses from one manufacturer. *L. monocytogenes* serotype 4b was isolated from patients and from packets of cheese. Although most of the cheese milk was pasteurized, about 10 percent was not.

Surveys in the USA and Europe (including the UK) have shown that *L. monocytogenes* may be found in a wide variety of soft cheeses (Gilbert 1987; Pini and Gilbert 1988; Greenwood et al. 1991). Experimental

production of cottage cheese with artificially contaminated milk confirmed that a proportion of the inoculum survived manufacture (which included cooking at 57.2°C for 30 min). Organisms could be recovered from more than one-third of samples by direct plating after storage at 3°C (Ryser et al. 1985). Ryser et al. (1985) also showed that listeria survive during the manufacture of Cheddar cheese and that numbers increase during the first 14 days of ripening. Thereafter, numbers decrease but may persist for months.

Sporadic cases of listeria infection have been associated with the consumption of soft cheeses (Bannister 1987; Azadian et al. 1989; McLauchlin et al. 1990). In 1987, cases of listeriosis in Switzerland were associated with Vacherins Mont d'Or soft cheese and investigations revealed that an outbreak lasting from 1983 to 1987 had involved 122 persons (with 34 deaths) (Bille 1990).

In an outbreak of listerosis reported in France (Goulet et al. 1995), 20 cases were identified between 2 April and 16 May 1995, including 11 in pregnant women, resulting in two spontaneous abortions, four premature births, and two stillbirths. The source of infection was one specific chain of Brie de Meaux (a raw milk soft cheese) production. This is the first outbreak of listeriosis, documented in France, which has been linked to the consumption of a raw milk cheese.

A study to identify the main hazards associated with the spread of *L. monocytogenes* in dairy products in Switzerland reviewed data from 1990 to 1999. Overall, 3 722/76 271 (4.9 percent) of samples were positive (Pak et al. 2002). Cheese-ripening facilities had the highest proportion of positive samples (7.6 percent) followed by small-scale dairies (4.4 percent). Contamination of these products is frequently associated with environmental contamination and in this study 9.5 percent of the samples of water, used for cheese washing, were positive. This may indicate that a preventative step can be introduced. 1 328/3 722 (35.7 percent) of isolates were serotyped with serotypes 1/2a, 1/2b, and 4b, accounting for over 90 percent of isolates. Hard and semi-hard cheeses were more likely to be contaminated with serotype 1/2b and soft cheeses with serotype 1/2a.

An outbreak of listeriosis associated with homemade Mexican-style cheese occurred during October to January 2000 in North Carolina, USA (MMWR 2001). Noncommercial, homemade, Mexican style fresh soft cheese produced from contaminated raw milk from a local dairy was implicated as the source. Once again, this outbreak highlights the risk of using raw milk in the preparation of dairy products.

An outbreak of febrile gastroenteritis following consumption of on-farm manufactured fresh cheese has been reported from Sweden (Carrique-Mas et al. 2003). Thirty-three consumers showed an attack rate of 52 percent. Illness was characterized by presentation of diarrhea (88 percent), fever (60 percent), stomach cramps (54 percent), and vomiting (21 percent) in the cases. Although gene sequences of verocytotoxin producing *E. coli* were detected in six subjects, 27/32 fecal specimens were positive for *L. monocytogenes*. Molecular profiles of *L. monocytogenes* from dairy, fecal, and clinical isolates were indistinguishable. Both microbiological and epidemiological evidence pointed to *L. monocytogenes* as the most likely source of this unusual outbreak. It is a timely reminder that *L. monocytogenes* can cause gastrointestinal symptoms and should be considered as a possible etiology in outbreaks of gastroenteritis associated with dairy products.

ESCHERICHIA COLI

Outbreaks of illness due to pathogenic *E. coli* have been recorded in association with cheese and it has become clear that serious infection with both enteroinvasive and VTEC may be acquired from contaminated cheese.

In 1971, there were 107 episodes of enteroinvasive *E. coli* illness involving 387 people in the USA (Marier et al. 1973). Imported French Brie, Camembert, and Coulommiers cheeses made at a single factory over a period of 2 days were implicated. A slowly lactose-fermenting strain of *E. coli* serotype O124:B17 was isolated from samples of cheese and from the feces of patients. Laboratory tests confirmed that the strain was invasive but not enterotoxigenic. There is no mention of whether the cheese milk had been pasteurized, but river water, used to wash the vats, was the suspected source of infection.

Epidemiological data incriminated French Brie and Camembert cheeses in a large outbreak of enterotoxigenic *E. coli* infection in 1983. This affected more than 3 000 people in the USA (Washington, Illinois, Wisconsin, and Georgia), as well as in Denmark, Holland, and Sweden (MacDonald et al. 1985; Nooitgedagt and Hartog 1988). *E. coli* serotype O25:H20 was isolated from fecal specimens and heat-stable (ST) toxin production was demonstrated. The plasmid profile of isolates from patients in Washington, Illinois, Georgia, and Wisconsin were similar. The illness was associated with cheese from two separate batches made at the same factory 46 days apart. There was no information about pasteurization and the source of contamination was not discovered. Cultures of cheese samples did not grow *E. coli* serotype O27:H20 but organisms binding antiserum to *E. coli* O27 were detected in one cheese specimen by solid-phase radioimmunoassay at a concentration of 10^4 organisms per gram.

There have been several reports of outbreaks of *E. coli* O157:H7 infection due to the consumption of cheese. One cluster of four cases occurred in a rural community of France and was linked to 'fromage frais' made with unpasteurized goats' and cows' milk on a farm. Four children aged from 9 to 15 months were affected, three during the spring of 1992 and one during the spring of 1993. All children had diarrhea, three

developed renal failure, and one child died. Samples taken from the farm yielded isolates of VTEC but not of *E. coli* O157 (Report 1994e). The first outbreak in the UK occurred in Scotland in 1994. Twenty cases of *E. coli* O157:H7 phage type 28 infection, in the Grampian region, were associated with a farm-produced cheese made with unpasteurized milk. Most of the patients had bloody diarrhea and one had HUS. *E. coli* O157 PT28 was also isolated from a sample of the cheese and typing of the isolates from the patients and the cheese by PFGE demonstrated that they were indistinguishable from one another (Curnow 1994). An outbreak associated with a hard cheese made from unpasteurized milk was identified in Lancashire, England in 1997. Five cases were associated with a strain of *E. coli* O157 PT 8 (Aird et al. 2000). Two cases had consumed the cheese, two cases had consumed different cheese from retail outlets that sold the contaminated batch, and there was no apparent connection in the fifth case. All five isolates from the human cases, from the cheese, and from cattle on the dairy farm producing the milk, had PFGE profiles that were indistinguishable. Enumeration of *E. coli* O157 in contaminated cheese revealed that the cheese was contaminated with between 5 and 11 CFU/g (Bolton, F. personal communication). This confirms the low infectious dose for this organism. This outbreak also highlights the potential for cross-contamination of other cheese products at retail outlets.

An outbreak involving four cases in a private house in Scotland in 1998 was also reported to be associated with the consumption of cheese (Task Force on *E. coli* O157 2001). Another outbreak was reported in Wisconsin, USA in 1998, associated with the consumption of fresh cheese curds. A total of 55 cases were linked to the outbreak of which 25 were admitted to hospital (MMWR 2000). Three outbreaks of *E. coli* O157 infection associated with cheese were reported in the UK in 1999. One of these was the outbreak linked to cheese made from goats' milk (see section on Goats' milk). The other two occurred in the north of England. One of these was associated with Cotherstone cheese, a specialist cheese made in the northeast of England from unpasteurized milk (CDR 1999). There were three cases of infection with *E. coli* O157 PT 21/28. Isolates were also obtained from several cheese samples but not from the farm producing the milk. All of the isolates had an indistinguishable PFGE profile. The remaining outbreak in 1999 occurred in the northwest of England. Four cases, one of which was a food handler, were linked to the consumption of a homemade cheese sold at a local restaurant (Aird et al. 2000).

The outbreaks in Scotland prompted a survey of *E. coli* O157 in high-risk foods such as raw meats, raw milk, and raw milk cheeses. The survey examined 739 samples of raw milk cheeses sampled at the point of sale by an enrichment culture-immunomagnetic capture method and did not find any positive samples (Coia et al. 2001). In contrast, a French survey that examined 180 cheeses made from unpasteurized milk, found that for all VTEC 30.5 percent were positive by PCR. None of these were *E. coli* O157 (Fach et al. 2001).

MICROBIOLOGICAL QUALITY CONTROL DURING MANUFACTURE OF CHEESE

In recent years, there has been increasing concern about pathogens in cheese and particularly of the risk of contamination with *L. monocytogenes* and *E. coli* O157 (Report of the Committee on the Microbiological Safety of Food 1990; Report of the Advisory Committee on the Microbiological Safety of Food 1995). It is clear that soft and fresh cheeses that develop pH values in excess of 5.0 should be considered as high risk for *L. monocytogenes* whereas soft cheese which maintains a pH of less than 5.0 is of lower risk. Hard-pressed cheese is also of low risk particularly if there is a long maturation time of 60 days or more, but no cheese is entirely without risk for contamination with *L. monocytogenes* or other pathogens if the hygiene during manufacture is poor or if the cheese has been manufactured from unpasteurized milk.

The industry has taken the problem of hygiene very seriously in the UK. The Creamery Proprietors' Association has published 'Guidelines for good hygienic practice in the manufacture of soft and fresh cheeses' (Report 1988) and the Milk Marketing Board has produced similar guidelines for the manufacture of soft and fresh cheeses in small and farm-based units (Report 1989). In addition, the joint FAO/WHO Codex Alimentarius Commission is at present drafting a code of practice for hygienic practice for the manufacture of uncured, unripened, and ripened soft cheeses (Alinorm 95/13). European Standards (Council Directive 92/46/EEC) and Dairy Products (Hygiene) Regulations (HMSO 1995) reflect the current anxiety about *L. monocytogenes* and are very stringent for soft cheese whether it is made from raw or pasteurized milk. *L. monocytogenes* must be absent from five samples of 25 g taken at the manufacturing premises and each 25-g sample must consist of five pieces of 5 g from different parts of the same product. In the USA, *L. monocytogenes* must be absent from cheese and other milk products, either home-produced or imported, and this is monitored by testing performed by the state and federal authorities.

In early 1995, 13 public health laboratories in England and Wales carried out a survey of the quality of a variety of imported and local soft and semi-soft cheeses purchased from retail outlets such as supermarkets, shops and delicatessens (Nichols et al. 1996). The cheeses were examined by internationally accepted methods according to a standard protocol to see how they compared when tested for *Salmonella* spp., *L. monocytogenes*, *S. aureus*, coliforms, and *E. coli*. Data obtained for 1 437 samples showed that generally the standard was good and that most cheeses would satisfy the legal requirements.

Cheeses made from unpasteurized milk were of a lower microbiological quality than those prepared from pasteurized milk and it was of concern that for 67 percent of the cheeses sampled, there was no information to enable the customer to determine whether the cheese was made from pasteurized milk or not. However, the isolation rate for *L. monocytogenes* was low for all cheeses (1.1 percent overall and 1.4 percent for cheese made from raw milk). This was significantly lower than that found during a previous survey in 1988–89 (Greenwood et al. 1991).

General principles of food microbiology	1	New approach to assuring the safety of foods	26
Factors influencing microbial growth in foods	1	Conclusions	27
Food processing and preservation	5	Acknowledgments	27
Bacteriology of specific food commodities	10	References	27

GENERAL PRINCIPLES OF FOOD MICROBIOLOGY

The field of food microbiology is very diverse, but it can be subdivided into three broad areas of study:

1. the utilization of microorganisms in the production of foods in order to enhance their nutritive value, organoleptic properties (color, odor, flavor, texture, etc.) and shelf-life
2. the control of spoilage of foods by reducing or eliminating their microbial content or by making the food environment unsuitable for the growth of spoilage microorganisms
3. the microbiological safety of foods, protecting of the food supply from those pathogenic bacteria that may be naturally present in foods or that may be introduced during processing and service.

The area of food safety is covered in other chapters of this treatise so will not be discussed in detail here. Local, national, and international food legislation is in place to protect the consumer from food-borne infections and intoxications of both microbial and nonmicrobial origin. These are aimed mainly at protecting the consumer from pathogenic microorganisms, so they will not be discussed here.

Not all microorganisms in foods are harmful and without some of them there would not be the great variety of foods that is enjoyed today. Some of the foods for which microorganisms (bacteria, yeasts, and molds) are essential to their production include cheese, yogurt, fermented sausages, sauerkraut, and a whole array of fermented delicacies (tempeh, tofu, soy sauce). In addition, the production of beer, wines, and other alcoholic beverages is dependent on the fermentation of appropriate substrates by yeasts. Production of a fermented product with the desirable characteristics already mentioned, but without the problems associated with the growth of spoilage organisms and pathogens, requires an intimate knowledge of the microorganisms involved in the three areas. This is particularly true with respect to their behavior in various food systems and their susceptibility to environmental conditions and chemicals. The branch of microbiology that deals with this specific area is called microbial ecology and forms the central focus of this chapter. This topic is addressed in a concise manner with important references for additional information. The two volumes on *Microbial ecology of foods* developed by the International Commission on Microbiological Specifications for Foods (ICMSF) are highly recommended as authoritative sources for additional information on this subject (ICMSF 1980, 1998).

FACTORS INFLUENCING MICROBIAL GROWTH IN FOODS

Foods are very complex biological materials that span a tremendous range in texture, fluidity, and nutritional

content. Nevertheless, there are several universal characteristics that can exert an influence on the growth of microorganisms. The major factors that must be considered are temperature, pH, and water activity (a_w). In addition, redox potential (*E*h) and the presence of organic acids, salts, and other chemicals can all influence the growth of microorganisms in foods. These factors can be considered as two groups, the intrinsic and the extrinsic factors (Mossel et al. 1995; Montville 1997a). Intrinsic factors are those inherent to the food itself such as naturally occurring compounds that stimulate or retard growth, compounds that are added as preservatives, redox potential, water activity, and pH. The primary extrinsic factors, those imposed from the outside, are temperature, humidity, and gas composition (controlled and modified atmosphere packaging).

Extrinsic factors

TEMPERATURE

Although microbial growth can occur over a temperature range of −8 to 90°C, in food microbiology the range of greatest importance is 1–50°C. Within this range the temperature can affect the duration of the lag phase, the rate of growth, the final population of cells, and the nutritional requirements. The temperatures immediately above and below the growth ranges of organisms may just retard growth, but if the temperature exceeds the upper limit, cell injury and cell death occur. The response of microorganisms to freezing temperatures is more complex and will depend on the composition of the microbial cell wall, the final temperature, and, more importantly, the rate of freezing.

Bacteria can be grouped according to their temperature ranges for growth: thermophiles (optimum 55–75°C), mesophiles (30–45°C), psychrophiles (5–15°C), and psychrotrophs (25–30°C). Many food-spoilage and most pathogenic bacteria are mesophiles. Psychrophiles are sensitive to temperatures higher than 20°C; therefore, they are not as important in foods as psychrotrophs, which have temperature maxima in the range of 30–35°C. The ability of psychrotrophs to grow at refrigeration temperatures make them important contributors to food spoilage. Bacteria in the genera *Acinetobacter*, *Alcaligenes*, *Bacillus*, *Chromobacterium*, *Enterobacter*, *Flavobacterium*, *Proteus*, *Pseudomonas*, and *Serratia* are important causes of the spoilage of foods, particularly those stored at refrigeration temperatures in order to increase their shelf-life. However, some food-borne pathogenic bacteria (*Listeria monocytogenes*, *Yersinia enterocolitica*) are psychrotrophic and disease outbreaks have occurred from contaminated food products that have been stored at refrigeration temperatures.

Effect of chilling

As the temperature is lowered to freezing point, the lag phase of bacterial growth increases greatly. All except the psychrotrophic group stop growing, thus giving the group a competitive advantage in foods held at low temperatures. Although the generation times of psychrotrophic organisms increase significantly at temperatures near freezing (for example, the generation time for *Pseudomonas fluorescens* at 0.5°C is 6.68 h), during refrigerated storage of foods for several days or weeks their populations can reach several millions. These bacteria grow using the food as their source of nutrients, with the result that the lipids, proteins, and carbohydrates in the food are broken down, producing degradation products of food components and the bacterial metabolic byproducts that are associated with food spoilage.

Effects of freezing

The response of bacteria to freezing ranges from little or no effect to varying degrees of injury and ultimately cell death (see Montville 1997a). Most spores and some vegetative cells can survive with almost no effect, but most non-spore-forming bacteria are affected to some extent. In general, gram-negative bacteria are more sensitive to freezing than gram-positive bacteria. Among those that are sensitive the consequences of freezing are sublethal cell injury and cell death. Cells that are sublethally injured are highly sensitive to the selective agents used in the selective enrichment and plating media used for the isolation and enumeration of food-borne bacteria. The use of these microbiological media to determine bacterial counts in frozen food products is most likely, therefore, to result in an underestimate of the microbial populations because of the failure of these sublethally injured bacteria to produce colonies. However, under appropriate cultural conditions, these sublethally injured bacteria may repair their damage and become fully viable and thus remain a threat to the integrity of the food.

The rate of freezing and the final storage temperature have an influence on bacterial injury and survival with the temperature range of −2 to −10°C being the most detrimental for bacteria. Slow freezing to approximately −10°C will cause maximal damage, whereas rapid freezing to −30°C or lower is likely to cause only minimal damage. Slow freezing also has a detrimental effect on the organoleptic characteristics of foods and is therefore not generally used as a means of bacterial inactivation.

Whether bacteria will grow in frozen foods after thawing will depend on the numbers and types that survived the freezing process and the conditions used for thawing. Uncontrolled thawing may result in a significant zincrease in the numbers of bacteria. When a large block of frozen food is thawed, the areas near

the surface will thaw much more rapidly than the core. Thus, bacteria near the surface of the food may start to grow and go through several generations before the center of the food has completely thawed. This is why it is considered safer to thaw frozen foods, particularly large blocks such as frozen turkeys, either at refrigeration temperature or rapidly by microwave heating rather than at ambient temperature.

Effects of heating

As the temperature rises above the optimum growth range, growth of bacteria ceases and injury and, ultimately, cell death occur. As with the effects of freezing, a mild exposure to heat can cause a sublethal injury in vegetative cells that is repairable. Spores are much more refractile to heat and may be activated to germinate. An exposure of 5 min at 80°C is typically used to inactivate vegetative cells and induce germination of spores. With further increase in temperature there is destruction of the bacterial population at an exponential (logarithmic) rate. Figure 1 shows a typical survivor curve for bacteria. By plotting the logarithm of the number of survivors against the time of heating at a specific temperature, a straight line is obtained because the rate of death is constant at a given temperature and is independent of the initial population of cells. The decimal reduction time (the time required to destroy 90 percent of the cells, *D* value) may be calculated from the

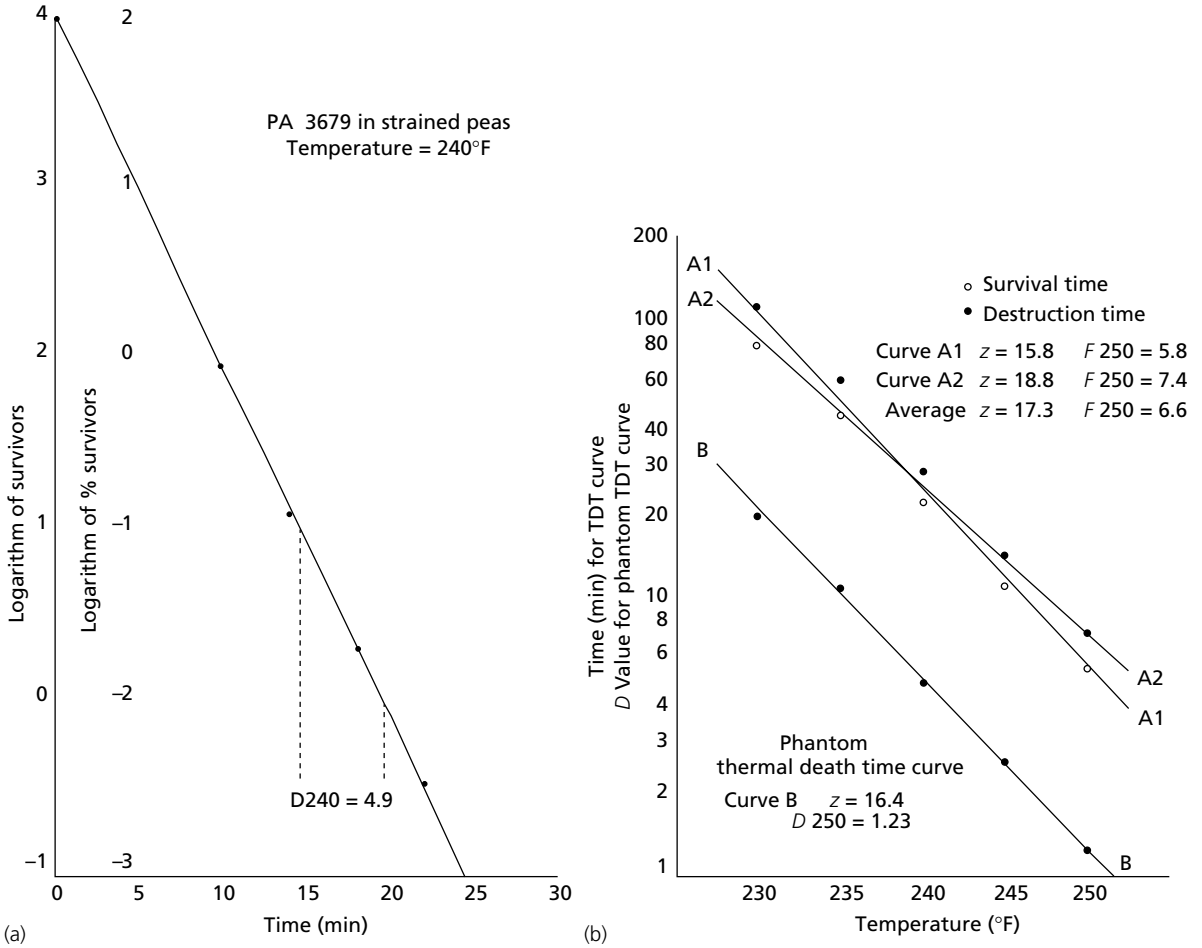

Figure 1 (a) *A typical survivor curve for bacteria. The test organism used to develop this curve is putrefactive anaerobe (PA) 3679, which is a non-toxigenic* Clostridium *species that has heat-resistance characteristics similar to those of* C. botulinum. *Therefore, PA 3679 is often used to determine or verify the thermal process conditions required to inactivate* C. botulinum *in specific foods. In this illustration, the* D *value for PA 3679 at 115°C (240°F) is 4.9 min.* **(b)** *An example of a thermal death time (TDT) curve. The* D *values are plotted on a logarithmic scale against the corresponding temperature on a linear scale to obtain the phantom TDT curves. These lines are described by the* D *value at a reference temperature (usually 60 or 121°C) and the slope of the curve (denoted by* z*).* z *is defined as the temperature that is necessary to bring about a ten-fold change in the* D *value.* F *denotes the time of treatment necessary to destroy microorganisms at a reference temperature, usually 60°C for vegetative cells and 121°C for spores. (Parts a and b based on Figures 7-7 and 7-8 from* Laboratory Manual for Food Canners and Processors*, vol. 1, National Canners Association Research Laboratories, 1968, AVI Publishing Company, Westport, CT, with permission from National Food Processors Association, Washington, DC.)*

survivor curve. The D value for the bacteria in Figure 1 is 4.9 min at 121 C.° The ordinate of the plot is on a logarithmic scale, thus it is evident that the population of bacteria would never be reduced to zero. It follows, therefore, that if a known population of bacteria in each of several unit volumes or containers were exposed to lethal heat treatments, a probability will always remain of a survivor in any one container. Such calculations are used to determine that the heat treatment to be applied to a specific type of food in a specific type of container will result in a probability of survival so low that it is acceptable. For example, a 12D process is generally used in commercial canning operations to assure that canned low-acid foods are free from the most resistant spores of *Clostridium botulinum* and the hazard of botulinum toxin.

The survivor curve gives information on the time of heat treatment required to destroy a certain proportion of bacteria at a specific temperature. The thermal death time curve is used to determine the effect of heat treatment of bacteria suspended in a medium at several temperatures. A thermal death time curve is constructed by plotting the $\log_{10}$ D values against the treatment temperature. The slope of the curve is denoted by the term z, which is the temperature in degrees Celsius required for the thermal death curve to traverse one log cycle. D and z values are used extensively in determining the heating requirement for foods preserved by pasteurization and sterilization.

Many factors influence the heat resistance of bacteria. These may be divided into three broad types:

1. the differences in heat-resistance characteristics of different species within a genus, strains within the same species, or spores versus vegetative cells
2. the environmental conditions to which the bacteria were previously exposed during growth
3. the properties of the food to which they are exposed during heat treatment (pH, a_w, salts and other compounds, type of food).

If these factors are not considered during the development of a thermal treatment process for foods, the outcome may be food spoilage and food-borne infection or intoxication.

GASEOUS ATMOSPHERE

The growth-limiting value of lowered partial pressure of oxygen (pO_2) or redox potential (Eh) is often combined with and reinforced by another inhibitory parameter, such as raised pCO_2. The composition of the gaseous atmosphere in which foods are stored may affect the fate of their microbial association more than by the oxygen partial pressure alone. A number of gases are utilized in the commercial preservation of foods: carbon dioxide, ethylene oxide, propylene oxide, sulfur dioxide, and ozone.

Intrinsic factors

WATER ACTIVITY

Microorganisms, in order to grow and metabolize, require water in an available form. The most useful measurement of available water is water activity (a_w). The a_w of a food or solution is the ratio of the water vapor pressure of the food (p) to that of pure water (p_0) at the same temperature. The a_w of pure water is assumed to be 1. When a solution becomes more concentrated with the addition of more solute (for example, salt, sugar, or other chemical) or the removal of water by drying, the vapor pressure decreases and so the a_w becomes a value of less than 1. The water molecules are oriented about solute molecules or become adsorbed on to insoluble food constituents and are thus less available for reactions. Most bacteria and fungi are unable to grow at an a_w of less than 0.90. Thus the dehydration of foods and the addition of salt and sugar are long-established food-preservation methods particularly in relation to food safety. Freezing can also reduce the a_w. However, some bacteria and fungi can grow at a_w values below 0.90 and are thus the organisms to be considered in preventing food spoilage. They are variously referred to as halophiles, xerophiles, and osmophiles, but these terms strictly should apply only to those organisms that can grow well at reduced levels of a_w but fail to grow at high levels. Gram-negative bacteria generally do not grow below a_w values of 0.97. Between a_w values of 0.98 and 0.93, gram-positive bacteria – Lactobacillaceae, Bacillaceae, and Micrococcaceae – become important. Below 0.93, food spoilage is caused primarily by yeasts and fungi. The only bacterial pathogen growing within this range is *Staphylococcus aureus*. Xerophilic fungi and osmophilic yeasts cause spoilage at a_w values below 0.85. Below an a_w of 0.60, microorganisms are unable to grow but they can remain viable for long periods.

pH

Bacteria have a minimum, optimum, and maximum pH for growth. The cell membrane is only slightly permeable to hydrogen or hydroxyl ions, and the cytoplasmic contents have a buffering effect, thus the pH inside bacterial cells is usually close to 7.0. The minimum pH values at which bacteria can initiate growth do vary. Some bacteria, such as the lactic acid bacteria, create an acidic environment by producing acids as metabolic products; they therefore gain a selective advantage over bacteria that are less acid-tolerant. Most bacteria are unable to grow at pH levels of less than 3.5 and those of importance in food-borne illness are unable to grow below about pH 4.5. High pH values also inhibit microorganisms. Egg white develops a pH of 9 because of the loss of CO_2 after the egg is laid; this protects the egg from bacterial invasion. Proteolytic organisms such as

Pseudomonas spp. can grow in moderately alkaline substrates. The antimicrobial effect of reduced pH depends on interactions with other factors (temperature, a_w, salt concentration).

REDOX POTENTIAL

The redox potential (*E*h) of a biological system is an index of its degree of oxidation and is an important selective factor in the food environment. Redox potential can denote the oxygen relations of a living microbe and may be used to specify an environment in which the organism can produce energy and new cells without recourse to molecular oxygen. Bacteria are classified as aerobic, anaerobic, facultative, or micro-aerobic based on the *E*h (ranging from positive values of about +300 mV (aerobe) to negative values of −420 mV (anaerobes)) required for their growth and metabolism. The *E*h of a food is related to its chemical composition (pH, concentration of reducing substances such as ascorbic acid, mercapto groups in proteins, reducing sugars, etc.) and the oxygen partial pressures existing over the food during storage. Gradients of *E*h may occur from the surface to the depth of a food where gaseous diffusion is restricted.

NUTRIENTS

The nutritional composition of a food has an influence on the type of bacteria that are likely to be present. Also, the nutrient requirements of bacteria may change depending on the environmental conditions in which they are grown. For example, bacteria generally become more nutritionally exacting at higher or lower growth temperatures or at lower a_w values. This may be due to inability to utilize particular nutrients as a result of impaired transport processes or from markedly reduced activity of critical enzymes. In general, most foods provide sufficient nutrients for most microorganisms. However, there is a wide range in nutrient complexity and availability; meats are generally considered highly nutritious and vegetables are considered to provide minimal nutrients.

Spoilage of starchy foods, such as potatoes and cereal grains, is caused primarily by bacteria that are able to break down the complex carbohydrates and that thrive in a minimum nitrogen and salts environment. Fresh vegetables are spoiled primarily by cellulolytic organisms. Bacteria with high lipolytic activity are favored in lipid-containing foods. Highly proteinaceous foods favor the growth of bacteria with complex nutritional needs. Nutrients control the rate of growth only when present at very low levels.

OTHER FACTORS

In addition to the factors discussed above, other factors that influence the growth of bacteria in foods are those natural components of foods, which have antibacterial properties (essential oils, tannins, and lectins). Animal foods contain many inhibitors of bacteria (lactenin in milk, lysozyme, conalbumin, ovomucoid, and avidin in eggs) but they usually have a narrow spectrum of activity and are quite labile. Therefore, they do not play a major role in preventing food spoilage.

Inhibitory factors may also be produced in foods as a result of processing. Sugar syrups undergo a browning reaction during storage, leading to the formation of furfural and its derivatives, which have antimicrobial properties. Similarly, the oxidative chemical deterioration of foods during storage also leads to the formation of products with antimicrobial properties.

FOOD PROCESSING AND PRESERVATION

Most agricultural products used for human food cannot be used directly without some form of further processing. Even fresh produce such as apples, potatoes, tomatoes, and beans must be washed, trimmed, sorted, and packaged. Often, more extensive processing is needed to convert raw agricultural commodities such as beef cattle, wheat kernels, and sunflower seeds into meat, flour and bread, and cooking oil, respectively. Thus, the primary objective of food processing is to convert raw agricultural commodities into processed foods or food ingredients. The food ingredients (flour, sugar, oil, etc.) may then be used in a secondary food-processing operation to manufacture products that are ready for human consumption. Generally, food-processing operations, particularly the secondary operations, integrate food-processing with food preservation. The two objectives of preservation are firstly to prolong the shelf-life of the processed food or food ingredient in order that it may be stored for long periods of time and distributed efficiently over great distances, and secondly to assure the safety of processed foods. Therefore, the food-preservation aspect of food processing deals with the control of microorganisms in foods to enhance the quality of foods, retard their spoilage, and eliminate pathogens. Strategies to achieve these objectives are developed on the basis of our knowledge of microorganisms and their response to the various extrinsic and intrinsic environmental factors discussed earlier (see also Table 1).

Preservation methods can be subdivided into three broad groups:

1. Physical methods involving treatments that inhibit, destroy, or remove undesirable organisms without antimicrobial additives or products of microbial metabolism, e.g. drying, temperature, radiation, high hydrostatic pressure, etc. (Farkas 1997).
2. Addition of chemical preservatives and natural antimicrobial compounds or utilization of their natural presence (Davidson 1997).

Table 1 *Preservation methods used in food processing*

Process	How preservation is accomplished
Well-established processes	
Drying (reduced water activity)	Reducing water activity below the level required for microbial growth
Chilling	Lowering of temperature to a point at which microbial growth is retarded or inhibited
Freezing	Changing of water to a form that microbes are unable to utilize Freezing temperatures also inhibit enzymatic activity and thus growth
Heating 1. Heat sterilization in hermetically sealed containers	Inactivating all viable forms of bacteria followed by storing under conditions that will prevent recontamination and chemical degradation
Heating 2. Pasteurization and other heat processes that do not completely eliminate microorganisms	Reducing spoilage bacteria to a significantly low level so that the shelf-life of the product is extended; vegetative cells of pathogenic bacteria will also be eliminated
Irradiation (ionizing)	a Inactivating all viable bacteria (sterilization) b Eliminating pathogens or prolonging storage time (pasteurization)
Pickling, salting, and sugaring	Reducing the acidity and/or water activity to levels that inhibit the growth of microorganisms
Fermentation	Controlling environmental conditions in order to favor the growth of beneficial microorganisms and retarding or inhibiting the growth of spoilage and harmful microorganisms
New/developing processes	
Gases	
Controlled atmosphere storage	Reducing oxygen content and increasing carbon dioxide content combined with chilled storage inhibits growth of spoilage organisms
Modified atmosphere packaging (MAP)/vacuum packing (VP)	Using combinations of CO_2, N_2, and O_2 to sustain visual appearance and extend shelf-life (MAP) Reducing the pressure of air and thus the O_2 levels to inhibit growth of some organisms (VP) Combined with the use of low-permeability packaging film
Heat treatments:	
Microwaves	Reducing process times and energy and water usage in some food processing areas. Microwaves create internal cellular friction that produces heat. Thermal nonuniformity is a problem
Ohmic heating	Using direct electrical heating by passing an electric current through the product. The heat produced results in microbial death
High hydrostatic pressure	Applying high or ultrahigh hydrostatic pressure that transfers through food instantly and uniformly. Probably alters permeability of cell membranes, leading to cell leakage
Electric-field effects	Applying external pulsed electric field (PEF) causing increase in membrane permeability and leakage of cell contents
Magnetic-field effects	Applying oscillating magnetic field impulses induces changes in ionic drift across the plasma membrane. May affect growth and reproduction of bacteria
Chemical preservatives (traditionally propionates, sorbates, benzoates, nitrites)	Adding to food retards growth of, or kills, microorganisms. Mainly bacterio- or fungistatic so will not preserve food indefinitely
Naturally occurring compounds, e.g. lactoperoxidase system, avidin, lysozyme	Formation of antimicrobial compounds naturally by enzyme activity or interference with transport or causes cell-wall degradation

3 Use of biologically based systems and probiotic bacteria, e.g. use of lactic acid bacteria (Montville 1997b).

Food dehydration

The basic principle of food preservation by dehydration is that microbial growth is inhibited if the water available for growth is removed, i.e. if the a_w is reduced. Among bacteria, gram-negative species have the highest a_w requirements, while the gram-positive, nonsporing bacteria are less sensitive to reduced a_w. Some yeasts and molds have lower a_w requirements than the bacteria.

Removal of moisture from a food by natural sun drying is the oldest food-preservation technique used by humans. The method is still used to preserve large quantities of food in many developing countries, particularly those with tropical climates. In modern food

processing, however, dehydration is accomplished in more controlled environments such as by the use of hot air (spray drying, fluidized bed drying, etc.), by contact with a hot surface (roller drying), or by sublimation of ice from frozen food (freeze drying). In addition to the inhibition of growth of microorganisms, dehydration also reduces the bulkiness of foods, making them more economical to store and transport. However, drying techniques have disadvantages: the acceleration of undesirable chemical reactions that occur in foods during exposure to high temperatures. Some foods withstand dehydration better than others. Freeze drying has the least undesirable effects on the food quality, but it is the most expensive and energy-intensive drying process.

It is important to control carefully the handling of foods both before and after the drying operation in order to prevent microbial spoilage and/or the spread of organisms that would lead to food-borne illness. The ingredients for dried food products must be of good microbiological quality and they should be stored under conditions that minimize microbial growth before the drying process. Some foods, such as meats, require heat treatment prior to drying. Cooking will reduce the moisture content by approximately 20 percent and will also reduce the number of viable bacteria present. Similarly, the blanching of fruits and vegetables or the pasteurization of liquid egg before dehydration will also reduce the total number of viable bacteria in the final product.

The bacterial numbers in dehydrated foods are usually lower than those found in the food before drying due to the inactivation of some, but not all, of the organisms by the process itself. Of the surviving bacteria, a proportion may be sublethally injured. The extent of cell death and cell injury occurring during the process will depend on the type of food (fat content, pH, presence of inhibitors, previous treatment history), the organism (species, strain, physiological age, state of the cells, and the concentration of cells), and the type of drying process.

Freeze drying is the most gentle of freezing methods, so it is likely to result in the greatest survival of bacteria. Thus, for example, the total bacterial levels in freeze-dried shrimps may be reduced by only one or two $\log_{10}$ units. If the shrimp had 10^6 bacteria per gram at the start of the freeze-drying process, the level at the end is likely to be of the order of 10^4 organisms per gram. In general, gram-negative bacteria such as *Pseudomonas* spp., *Escherichia coli*, and *Vibrio* spp. do not survive freeze drying as well as gram-positive bacteria. Cells of *Lactobacillus acidophilus* that survived freeze drying revealed damage to both cell membrane and cell wall (Brennan et al. 1986); cellular DNA may also be damaged.

During spray drying, finely aerosolized liquid food is brought into contact with hot air to remove the moisture. Bacteria present are affected by the aerosolization, heating, and drying. There may be changes in the outer layer of the cell envelope, cytoplasmic constituents may leak out, and they may lack control of ion transport (Banwart 1987). Survival of bacteria in the spray-drying process is related to the outlet temperature (Miller et al. 1972; Thompson et al. 1978). During the spray drying of liquid egg, a lower temperature during drying together with rapid cooling of the product after drying enhance the qualities of the dried egg product. However, the same conditions are favorable for the survival of salmonellae. Over 99 percent of salmonellae cells are killed during spray drying if the inlet temperature is maintained at 121°C and the outlet temperature at 60°C (Banwart 1987). Although dried fish products can be produced with bacterial loads as low as 10^2 cfu/g, commercial dried fish may have bacterial loads as high as 10^7 cfu/g.

All the bacteria present in dried foods are not inactivated during the drying process so growth of the surviving viable and sublethally injured bacteria will be initiated when environmental conditions become appropriate. It is therefore critical to maintain product integrity by storing dried foods under the correct conditions. Dried foods must be stored in moisture-impermeable containers under low humidity to prevent unacceptable increases in the a_w. Salmonellae that survive the drying of eggs are inactivated during the storage of the dried product even at low temperatures. In dried albumen, salmonellae can be inactivated by storage of the product at 50–60°C for up to 7 days. Generally, bacteria survive better in dried foods under vacuum than in the presence of oxygen.

Chilling and freezing

Clarence Birdseye in the USA and Bill Heeney in Canada pioneered the frozen-food industry in North America. The rapid expansion in frozen-food technology paralleled the engineering developments in the refrigeration industry. Although frozen foods are expensive to process and store, food-quality deterioration is greatly diminished by freezing compared with dehydration and heat sterilization.

The obvious major difference between refrigerated food and frozen foods is the temperature at which the food is held. Another important difference is that the water in the refrigerated food is still available for growth of psychrotrophic spoilage bacteria and pathogens, i.e. it still has a high a_w.

The freezing of food makes water unavailable to microorganisms by immobilizing it in the form of ice. The low temperature at which frozen food must be held also deters the growth of microorganisms. Freezing is not effective in inactivating bacteria, although some reduction in bacterial content is achieved. Gram-negative bacteria are more susceptible than

gram-positive bacteria to freezing-induced injury and death.

Several factors influence the effectiveness of freezing as a preservation technique. These include the initial microbial load, the physical dimensions of the product to be frozen, the packaging material, the freezing rate, the time and temperature of subsequent storage, the degree of fluctuation in the storage temperature, and the time–temperature conditions used for thawing the product. The freezing process can be divided into three stages:

1. cooling down from the initial temperature of the food product to the temperature at which freezing begins
2. chilling at the latent heat plateau when there is no temperature change but phase change of water to ice occurs
3. further cooling to the final storage temperature.

The initial cooling of the food may inactivate a proportion of the microorganisms present due to cold shock; the decrease in temperature also reduces the growth rate of psychrotrophic bacteria. During the phase transition from water to ice, bacteria may be killed as a result of mechanical injury to the cell wall and cell membrane through the formation of ice. The growth of most cold-tolerant microorganisms is inhibited during further cooling until it ceases at about −8°C. Slow freezing to a final temperature of −10°C is more lethal to bacteria than rapid freezing to −20°C. During slow freezing, ice crystals form and soluble solids are concentrated that affect the stability of cellular proteins. However, there are also adverse effects on the texture and structural integrity of the food.

The freezing process may cause inactivation of 10–60 percent of the total bacterial population depending on the characteristics of the food and the organisms present and the conditions of freezing. Bacterial spores are unaffected by freezing; and neither are bacterial toxins inactivated. It is possible, therefore, for food intoxication to result from consumption of a frozen food in which the toxin had been produced by bacterial growth prior to the freezing process.

Food preservation by heat treatment

HEAT STERILIZATION IN HERMETICALLY SEALED CONTAINERS

The technology of the conventional canning process may be summarized as filling food into containers of metal, glass, or thermostable plastic, or into multilayered flexible pouches, sealing the containers, and then applying the heat treating process. This process is sometimes called 'terminal sterilization' and is designed to destroy large numbers of *Clostridium botulinum* spores should they be present. It also reduces the chances of survival of spores of spoilage organisms that are even more heat-resistant that *C. botulinum* spores. After heating, the containers must be cooled and handled in a manner that will assure container integrity and avoid contamination resulting from leakage.

The sterilization parameters vary greatly and depend on the food composition. One of the most important factors in determining the correct time–temperature combinations to use for a particular food is the pH of the product. Low-acid foods (pH >4.5) and foods of a_w >0.85 are likely to support the germination and outgrowth of spores of *C. botulinum* and the subsequent production of botulinal toxin. Specific regulations exist, therefore, in most countries for the processing of low-acid foods in hermetically sealed containers. The minimum heat treatment process for these foods is a 12*D* reduction process based on the thermal death times determined for each specific food product. The 12*D* reduction process is sufficient to reduce the probability of survival of *C. botulinum* spores to no more than 1 in 10^{12} cans (containers) processed.

The manufacturing process must include appropriate good manufacturing practices before the heat-sterilization step. The heat-sterilization step will not inactivate preformed heat-resistant toxins. Therefore, the quality of the ingredients must be evaluated and their handling must be designed to prevent bacterial contamination and/or growth. If acidification of the product is possible, i.e. it does not adversely influence the organoleptic characteristics of the food, it should be included because acidified food products require much less heat treatment than low-acid foods to assure their safety. Examples of food products that are amenable to acidification include artichoke hearts, pimientos, and many pickles.

The *D* and *z* values were described earlier in this chapter. Another term that figures in the calculation of heat treatment parameters for foods is the *F* value. This is defined as the time required to inactivate a given number of bacteria at a specified temperature and is usually 121°C for spores and 60°C for vegetative cells. *F*60 is the thermal death time (TDT) at 60°C and *F*121 the TDT at 121°C. In 1922, Esty and Meyer indicated that the *F*121 for *C. botulinum* spores was 2.78 min. Thus, the generally accepted minimum treatment for achieving a 12*D* reduction of *C. botulinum* spores is 3 min at 121°C. The thermal treatments applied to commercially canned cured meat products is well below this because the heat treatment is supplemented by the inhibitory effect of curing salts on the germination of spores of *C. botulinum*. Low-acid canned uncured meats are treated at an *F*121 of 6 min. Using the *D*, *F*, and *z* values, the rate of heat penetration in a specific food, the pH of the food, and the temperature of the pressurized container in which the cans of food are heated, a thermal process for that specific food can be calculated. Experimentally inoculated packs are processed at the calculated thermal process conditions to evaluate the adequacy of the process. *Clostridium sporogenes* strain PA3679 is the usual test organism in inoculated pack

studies because the spores of this non-toxigenic strain have a greater heat resistance than those of *C. botulinum*.

Container integrity is essential for maintaining the safety of commercially sterilized food products and for preventing spoilage. If the cans develop leaks, air or water may enter and introduce spoilage bacteria. In some instances the water may also carry pathogenic bacteria. Effective control measures to prevent post-processing contamination of cans include assuring the proper function of sealing equipment, disinfection of the water used to cool the containers after heat treatment, maintaining the containers in a dry condition as far as possible, and avoiding abuse of the containers.

Heat-sterilized foods in cans are subject to a number of different kinds of spoilage. Spoilage of the food may occur prior to processing or may be due to an inadequate heat treatment or to post-process contamination. Spoilage resulting from inadequate heat treatment is due to heat-resistant spores while inadequate cooling or a high product storage temperature leads to spoilage by thermophilic bacteria. Spoilage following water leakage into the can usually involves nonspore-forming bacteria, yeasts, and molds. The visual signs of spoilage may be bulging of the can at one or both ends, although the growth of the 'flat sour' organisms (*Bacillus coagulans* and *Bacillus stearothermophilus*) does not result in bulging of cans. Occasionally cans may swell due to the effect of acid foods on poorly coated internal can surfaces; the hydrogen produced causes the swelling.

ASEPTIC PACKAGING

In aseptic packaging, the food is sterilized, cooled, and transported under aseptic conditions to the presterilized container. The product is filled into the container and sealed under aseptic conditions. The end product is thus a hermetically sealed container holding a commercially sterile food that can be stored at ambient temperature for prolonged periods.

PASTEURIZATION

Heat treatment of foods below the temperatures needed for sterilization is termed pasteurization. Generally, this type of heat treatment is used to prolong the shelf-life of specific foods that do not withstand the sterilization process. Pasteurization is usually used to inactivate specific groups of bacteria, particularly pathogenic bacteria, and to reduce the numbers of spoilage bacteria. The process is most commonly applied to milk and dairy products, but in addition pasteurization is used to control microorganisms in liquid egg products, alcoholic beverages, smoked fish, and high-acid products (fruit juices, pickles, sauerkraut, and vinegar).

Food regulations in developed countries require that all liquid, frozen, and dried whole egg, yolk, and white be pasteurized to destroy viable salmonellae. However, the temperature and time requirements vary from country to country, ranging from 62°C for 150 s to 68°C for 180 s.

Irradiation

The process of food irradiation uses high-energy electromagnetic radiation (γ-rays) from radioactive isotopes such as caesium-137 or cobalt-60, or electrons from linear accelerators (Banwart 1987). These types of radiation are chosen because they produce the desired effects with respect to the food, they do not induce radioactivity in foods or packaging materials, and they are commercially economical (Farkas 1997). Radiation treatment of foods can have a range of effects depending on the level of the dose applied. Low doses of only 1–2 kGy can inhibit sprouting of vegetables (potatoes and onions) and delay ripening of fruits and vegetables. Higher doses (1–5 kGy) destroy parasites and pathogenic bacteria in meats, poultry, and fish, reduce viable bacteria in dried products such as spices and herbs, and destroy spoilage organisms to extend the shelf-life of perishable and semiperishable foods. The highest doses (20 kGy and above) can produce commercially sterilized foods (WHO 1988).

The ionizing radiation doses required for the destruction of microorganisms in foods will vary widely and are dependent on the type and numbers of cells, type of substrate or suspending medium, moisture content, oxygen tension, temperature, or the presence of protective compounds. Ionizing radiation causes cell death directly by attacking the DNA and causing single- or double-strand breaks or indirectly by the primary water radicals $^{\cdot}H$, $^{\cdot}OH$, and e_{aq}^{-}. The most important in DNA damage is the OH radical: those formed in the hydration layer around the DNA molecule are responsible for 90 percent of the DNA damage (Farkas 1997). The resistance of an organism to ionizing radiation is, in part, dependent on the capacity of the organism to repair the damage to its DNA. Most can repair single-stranded breaks, but the more sensitive organisms (e.g. *E. coli*) cannot repair double-stranded breaks. Bacterial spores are highly resistant to ionizing radiations due to the low water content of the spore protoplast; reported *D* values (decimal reduction dose) for spores of *C. botulinum* type A are 2.18–2.35 kGy in cured ham. Generally, gram-positive bacteria are more resistant than gram-negative bacteria: *Pseudomonas* spp., *E. coli* and *Proteus* spp. are very sensitive to ionizing radiation. Microbial radiation resistance in frozen foods is about two- to three-fold higher than at ambient temperature due to immobilization of the free radicals.

Although ionizing radiation has the potential to enhance the quality of our food supply and to increase its safety, it has not gained wide acceptance for use in

food processing because of the public's fear of anything 'nuclear.' However, its use is permitted in a number of countries with doses up to 10 kGy for extension of refrigerated shelf-life and inactivation of nonsporing pathogens for poultry, pork, and sausages (WHO 1994). Ionizing radiation treatment has been approved in the USA for fruits, vegetables, spices, poultry, and pork, but it is not commercially used. In the UK, regulations (Statutory Instrument 1990a, b) came into force in 1991 introducing food labeling and a licensing system for food-irradiation plants including cover of all irradiated food from the processing plant to the supermarket shelf. The regulations state that food must be of good microbiological quality before it is irradiated.

Hurdle technology

Manipulation of the effect of a number of environmental factors together to inhibit microbial growth, for example pH, salt concentration, and temperature, is the basis of multiple 'hurdle technology.' Instead of setting one environmental factor to the extreme limit for growth, hurdle technology 'de-optimizes' a variety of factors. Whereas growth of food-borne pathogens is limited at a water activity of 0.085 or a pH of 4.6, similar inhibition may be obtained at pH 5.2 and a_w 0.92. In maintaining intracellular pH and accumulating compatible solutes in the low a_w, i.e. in maintaining homeostasis, the cells channel energy needed for biosynthesis. Thus their growth is inhibited. If this energy demand exceeds the energy producing capacity of the cells, they die (Montville 1997b).

BACTERIOLOGY OF SPECIFIC FOOD COMMODITIES

Meats

Reviews of the microbiology of meat and meat products are given by Davies and Board 1998 and ICMSF 1998.

Meat can be defined as the flesh of animals used as food and now tends to exclude poultry and fish. It is primarily the skeletal musculature tissue but commonly includes various organs that are regarded as edible (this may vary between countries). Thus meat comprises the musculature of 'red-meat' mammals, most commonly bovines, ovines, and porcines. Depending upon country and religion, the meat supply may be beef, pig, lamb, goat, camel, buffalo, deer, or horse. Within a species, the proportions of muscle, fat, and connective tissues can vary from one breed to another, and with age and rearing conditions, particularly the energy content and quantity of feed. Young animals deposit mainly protein; fat deposition increases with physiological age at the expense of protein. The amount of connective tissue varies in different muscles: those with little are tender to eat even after mild cooking (e.g. grilling), whereas those containing larger amounts are considered tough unless subjected to more severe and prolonged cooking to gelatinize the collagen. With increasing age the collagen of the musculature becomes more heavily cross-linked. A proportion of cross-links are heat-stable, causing meat from older animals to be less tender unless cooked thoroughly (e.g. by cooking under pressure). Some fat is necessary for maximum eating quality, particularly for succulence, and for the full development of the cooked meat flavor, but there is sufficient intramuscular fat for these purposes in all but unusually lean animals.

The contractile elements of the muscle, the myofibrils, also contribute to meat texture. The ultimate pH of meat is proportional to the amount of lactic acid formed during postmortem glycolysis, which is dependent on the amount of glycogen in the muscles at death. In a muscle rested before slaughter almost all the glycogen is converted to lactic acid (a concentration of approximately 1 percent lactic acid corresponds to pH 5.5), giving a muscle of normal appearance and texture. Low glycogen levels result in muscle of high ultimate pH. Such muscles often appear dark and, in addition, are firm and dry (DFD). In stress-susceptible animals, especially certain cross-bred pigs, excitement or stress before slaughter causes rapid conversion of muscle glycogen to lactic acid, resulting in a low pH before the muscles have cooled. This denatures sarcoplasmic protein and reduces the water-holding capacity of the tissue, giving a pale, soft, exudative (PSE) condition.

Meat comprises contractile myofibrillar elements and soluble sarcoplasmic proteins with up to one-quarter by weight connective tissue and as much as one-third fat. The presence of connective tissue seems unimportant microbiologically, but the relevant properties of the fat differ considerably from those of the muscle.

Intensive rearing of cattle, sheep, and pigs has resulted in a large international trade in meat. This international trade developed initially by transporting carcasses but, in transporting prime cuts, has become predominantly an intermediate stage between the carcass and the retail-sized portion. Muscle contains approximately 75 percent water and a variety of substrates for microbial growth, including carbohydrates, amino acids, lactic acid (Dainty et al. 1983; Lawrie 1985; ICMSF 1998). The a_w of meat is high, approximately 0.99, which makes it a suitable growth medium for most microbes. Only if most of the water is removed (e.g. by drying) will the a_w be reduced sufficiently to affect microbial growth.

Within the normal pH range of meat (approximately 5.4–7.0), values approaching 5.4 are less favorable to the growth of many of the important bacteria; the lower pH values are particularly important in maintaining the microbiological stability and safety of cured meat products.

The redox potential of meat has been claimed to be important in determining the nature of microbial spoilage, but its exact role in permitting or preventing the growth of microbes has not been fully elucidated, probably due to unresolved experimental problems of controlling and measuring redox potential. Tissue respiration of oxygen continues after death; because the supply of oxygen via the blood has ceased, the oxygen content and redox potential of muscle fall, leading to anaerobic conditions even at only a few millimeters below the surface. However, microbial growth in the deep musculature is rare, except where refrigeration is inadequate (Gill 1979; Roberts and Mead 1986).

MICROBIOLOGY AT PRODUCTION

In industrially developed countries, the change in eating patterns and in technological developments in animal husbandry, meat production, food processing, and preservation have led to an enormous increase in the range of meat products available. Novel methods have also been developed to maximize the recovery of meat from the carcass. Many meat products spend weeks, or even months, in distribution and storage before being offered for sale alongside the fresh product. The lower the number of microbes present initially, the longer the shelf-life of the perishable product providing storage conditions are correctly controlled.

Bacterial contamination of carcass surfaces can occur during slaughter and dressing procedures from a variety of sources, such as the hide, intestinal contents, contact surfaces, and handling by workers. Fecal contamination, routinely experienced during the normal slaughtering process, contributes high levels of bacteria (typically >10 000 cfu/cm^2). Good sanitary practices during slaughter, trimming of visible fecal contamination, and washing of carcasses with or without sanitizers are the approaches usually employed to minimize the contamination of carcasses (Dickson and Anderson 1992). The addition of chlorine, acetic acid, or lactic acid to the wash water reduces the bacterial load on the surface but does not significantly increase the shelf-life or completely eliminate pathogenic bacteria (Prasai et al. 1995). Higher water pressures (>13.8 bar) during spray washing are more effective in reducing bacterial loads on the surfaces of carcasses. Also, a two-step washing procedure with a low-pressure, hot-water (72°C) wash followed by a high-pressure, low-temperature (30°C) wash has been reported to be effective in reducing surface bacterial contamination (Gorman et al. 1995; Dorsa et al. 1996).

The microbial flora of the surface of freshly slaughtered carcasses, usually in the range of 10^1–10^3 cfu/cm^2, is primarily mesophilic, having originated in the alimentary tract and on the external surfaces of the live animal. Contamination from the slaughtering environment is also predominantly by mesophiles; psychrotrophs originating from soil and water are also present, but at much lower levels. Usually carcasses are cut into smaller portions in refrigerated work rooms, where most bacteria on the surfaces of processing equipment are psychrotrophic in nature. During refrigerated holding, the microflora of meats begins to shift towards psychrotrophs of the *Pseudomonas–Acinetobacter–Moraxella* group. These organisms are ultimately responsible for the spoilage of refrigerated meats. The spoilage is primarily a surface phenomenon resulting in the formation of slime and off-odor. The shelf-life of refrigerated meats is extended by controlling the factors contributing to the growth of psychrotrophs, namely moisture levels at the surface of the meat, initial load of psychrotrophs, pH, oxygen tension, and temperature. Wrapping meat in oxygen-impermeable films retards surface growth and favors the growth of microaerophilic bacteria, such as lactobacilli and *Brochothrix thermosphacta*, over the *Pseudomonas–Acinetobacter–Moraxella* group. The bacterial load of chilled meats at the retail market may bear no relationship to the load at the processing plant because the psychrotrophs continue to grow during transportation and storage.

The microbiology of meat other than the musculature is relatively poorly researched, with few publications on the microbiology of edible offal such as heart, liver and kidney, despite their increasing use in meat products. The initial contamination of offal is often higher and there is more likely to be contamination with potential pathogens than in skeletal muscle. The chilling process is often done poorly and offal may be packed while still warm before transport to chillers or freezers. Slow cooling results in significant increase in microbial numbers. Contacting surfaces remain moist and may be an important factor in the lower incidence of *Campylobacter jejuni* (*C. coli*) on retail carcass meats compared with offal.

Coliforms, *E. coli*, enterococci, *Campylobacter* spp., *Staphylococcus aureus*, *Clostridium perfringens*, *L. monocytogenes*, *Y. enterocolitica*, and *Salmonella* spp. are often present on fresh tissues because the slaughtering process does not currently include a bactericidal step. The enterohemorrhagic or verotoxigenic strain (EHEC or VTEC) *E. coli* O157:H7 is a recently emerged pathogen that has caused major food-borne disease outbreaks, with undercooked ground beef, particularly as hamburgers, commonly implicated. Enterohemorrhagic *E. coli*, of which *E. coli* O157:H7 is the most frequently encountered serotype (although other serotypes including O26:H11, O103, O104, and O111 have been implicated in cases of bloody diarrhea), have the ability to adhere intimately to human intestinal cells by an attaching and effacing mechanism and produce one or more phage-encoded Shiga-like toxins. In addition to hemorrhagic colitis, *E. coli* O157:H7 may cause serious life-threatening clinical diseases such as hemolytic–uremic syndrome and thrombotic thrombocytopenic purpura

in children and the elderly. *E. coli* O157:H7 has a low infectious dose (estimated to be of the order of 10–100 cfu) and can be spread by person-to-person contact in day-care settings (Griffin 1995).

Cattle are primary reservoirs of *E. coli* O157:H7. The carcass may become contaminated during slaughter and dressing operations. Meat from a single carcass may contaminate large batches of ground beef because of the tendency to mix and blend meat from several animals from different farms during production. Witholding feed, as is normally done before shipping or slaughter, to reduce fecal contamination, can lead to intestinal outgrowth and colonization by both *E. coli* O157:H7 and salmonellae due to the disruption of normal fermentation in the rumen (Rasmussen et al. 1993). Shedding of salmonellae and *E. coli* O157:H7 by feedlot cattle after shipping appears to be directly related to their length of stay in pens (National Animal Health Monitoring System 1995). *E. coli* O157:H7 have also been isolated from lamb products (Chapman et al. 2000).

Few studies have been conducted on the prevalence of pathogenic bacteria at different locations on pork carcasses. Epling et al. (1993) reported that the prevalence of *Salmonella* spp. and *Campylobacter* spp. on shoulder and ham surfaces was as great or greater after 24 h of chilling at 4°C when compared with the numbers at slaughter. Swine are the main reservoir of *Y. enterocolitica* where the organism appears to have a predilection for the tonsils and tongue. Careful removal is needed to prevent carcass contamination. Outbreaks of *Y. enterocolitica* infections have occurred in the USA caused by raw chitterlings (pork intestines); adults handle the chitterlings and then transmit the organisms to their infants and children (Lee et al. 1990). Consumption of undercooked pork in some European countries has also been implicated (Tauxe et al. 1987; Ostroff et al. 1994).

Salmonellae, campylobacters, motile aeromonads, and *Y. enterocolitica* have been isolated from lamb carcasses sampled at commercial abattoirs (Sierra et al. 1995; Chapman et al. 1997). Horizontal transmission of infection and persistent shedding (for 2 weeks) of *E. coli* O157:H7 were demonstrated after oral inoculations of lambs with 10^5–10^9 cfu of the organism. As observed in cattle, withholding of feed from lambs causes increased shedding of *E. coli* O157:H7 (Kudva et al. 1995). In nature, however, sheep appear to harbor *E. coli* O157:H7 and other enterohemorrhagic *E. coli*.

Irradiation treatment has the potential to reduce contamination of meat with pathogens signficantly, while the shelf-life of the meats is also prolonged. The effects will vary with animal species and type of packaging. Irradiation of ground beef in oxygen-permeable packaging with 1 kGy of γ-rays will reduce the numbers of *Salmonella* spp. *Y. enterocolitica*, and *Campylobacter* spp. but may cause objectionable odor, color, and flavor changes, but there are no odor problems with pork. In zvacuum-packaged beef a 2-kGy treatment at 25°C eliminates pseudomonads, enteric bacteria, and enterococci and causes fewer odor and flavor problems (Lee et al. 1996).

SHELF-STABLE RAW SALTED AND SALT-CURED MEATS

Salting of foods is one of the oldest methods of food preservation. Salting of meats was extremely common practice before the introduction of home refrigeration units and raw salted products continue to be produced and sold, especially in predominantly agricultural areas. Salt pork, dry cured bacon, and country-cured hams are still produced in volume. In the process of dry curing, pieces of meat are coated with salt and stored in bins below 10°C. Special care must be taken to ensure that the salt is applied to all folds and crevices in the meat to prevent bacterial growth leading to spoilage. Water is released from the meat by the action of the salt. At intervals, the pieces of meat are recoated with salt. At the end of the salting period, the product contains high levels of salt and is racked and held at ambient temperature until the surface dries. Finally, the meat is rubbed with salt and spices, netted, and sold. With such a high salt content, the product does not require refrigeration. The main microbial flora of these products after curing and drying are members of the Micrococcaceae, with lactic acid bacteria and yeasts as minor components. *Staphylococcus aureus* can be found in low numbers. Products sold as country-cured hams or bacon are similarly processed, except that sodium nitrite is used in combination with a lower level of sodium chloride. The product is hung to dry at ambient temperature for 35–140 days before removal for sale as a shelf-stable product. During the curing process, the salts penetrate and equilibrate in the tissue. The combined action of reduced water activity and the preservative effect of nitrite inhibit or inactivate the bacteria that cause spoilage or human illness. During the subsequent drying period, salt-tolerant enterococci and micrococci begin to grow and predominate; they also suppress the growth of the undesirable bacteria.

PERISHABLE RAW SALTED AND SALT-CURED MEAT

Fresh sausages are the most commonly encountered perishable raw salted meat products, but the salt content used is not sufficient to make the product shelf-stable. The method of packaging is the major factor that determines the predominant spoilage flora. Fresh sausage sold in bulk on trays or stuffed in casings is highly perishable, with a shelf-life of just a few days; psychrotrophic pseudomonads are the primary spoilage organisms. The shelf-life of fresh sausage can be extended to 1 or more weeks by wrapping the sausage in oxygen-impermeable film. The restriction of oxygen favors the growth of lactic-acid-producing bacteria, which impart a tangy

flavor to the product. Large quantities of perishable meat products are cured with salt, sodium nitrite and nitrate, ascorbic acid, and other flavoring materials. Most of these are cooked before shipping from the processing plants, although some are sold with little or no heat treatment and must be cooked before eating. Some raw cured meats are heated or smoked to different degrees to produce dry surfaces and a smoked flavor; these procedures may also extend their shelf-life by reducing the numbers of bacteria.

PERISHABLE COOKED UNCURED MEATS

Most pork products are given a heat treatment sufficient to destroy all nonspore-forming bacteria present, with only spores at a level of approximately 10^2/g surviving. Beef products are usually processed at a lower temperature sufficient to destroy nonspore-forming pathogens, but not necessarily some of the thermoduric bacteria such as enterococci. Microbial levels in the final product depend on the initial microbial load and types of bacteria, the cooking time and temperature, and the storage temperature and time. In meats that are only lightly cooked, i.e. where the center is still essentially raw ('rare'), the center temperature may not have been sufficient to eliminate even relatively heat-sensitive organisms, including those of concern such as *Salmonella* spp., *Campylobacter* spp., *E. coli*, and *Y. enterocolitica*. The color change in meat from red to gray associated with cooking occurs at temperatures approaching 60°C. Freshly cooked meat products may contain only about 10^2 cfu/g, but post-cooking handling and packaging may result in contamination with spoilage bacteria and pathogens. Cooked uncured meat products are ideal substrates for microbial growth. They are highly nutritious, they have favorable pH and a_w, and the cooking process reduces or destroys the competing microflora. Many of these foods are frozen for shipment and distribution. However, if they are held at above freezing point for 1 to several days, spoilage will occur due to the growth of enterococci, pseudomonads, lactic acid bacteria, and other psychrotrophs.

PERISHABLE COOKED CURED MEATS

Precooked cured meats include a variety of popular luncheon meats including frankfurters, bologna, and ham. The heating process applied destroys the normal meat microflora apart from spores and possibly thermoduric bacteria. During chilling, holding, and packaging, exposed surfaces may become contaminated. Salt and nitrite used in the curing process may inhibit the growth of any surviving or contaminating organisms. On prolonged storage at refrigeration temperatures, spoilage with slime formation occurs primarily due to enterococci, micrococci, lactic acid bacteria, and yeasts. If oxygen-impermeable film is used for wrapping the product, spoilage is primarily due to lactic acid bacteria. *Brochothrix thermosphacta* can form a significant part of the spoilage flora of vacuum-packed products, but growth of this organism in relation to lactic acid bacteria is reduced by a lower nitrite concentration, lower pH, and lower packaging film permeability.

CANNED CURED MEATS

Canned cured meats may be shelf-stable or perishable. Shelf-stable products include canned wieners, corned beef, frankfurters, meat spreads, luncheon meat, small canned hams, canned sausages covered with oil, and vinegar-pickled meats. Stability and safety of these products depend on the combined effect of heating and other factors that will inhibit the growth of surviving spores (e.g. salt, nitrite, a_w) and a sealed container to prevent post-process contamination. Some of these products, e.g. canned wieners and frankfurters, are given a 'botulinum cook' under the regulations applicable for low-acid foods packed in hermetically sealed containers. Canned sausages covered in oil do not spoil unless the a_w is higher than recommended (ranging from 0.86 to 0.92, depending on the product) and the vacuum seal is broken. Pickled pigs' feet and pickled sausages are immersed in vinegar-brine and are preserved by low pH, acetic acid, little or no fermentable sugar remaining in the tissue, and/or an airtight package.

Perishable canned cured meats made from pork must be stored refrigerated. They contain nitrite and salt at levels used to prepare shelf-stable products, but their heat treatment is inadequate to inactivate spores. Perishable canned cured meats may be shelf-stable for up to 3 years if properly processed and refrigerated. Spoilage is primarily due to psychrotrophic, thermoduric nonspore-forming bacteria (e.g. enterococci, *Lactobacillus viridescens*) that were present at abnormally high levels or survived an inadequate processing.

FERMENTED AND ACIDULATED SAUSAGES

Fermented products such as Thuringer, summer sausage, pepperoni, Lebanon bologna, Genoa salami, and cervelat depend on lactic fermentation and low water activity for preservation. At the end of fermentation, lactic acid bacteria exceed 10^8 cfu/g. Previously, the primary safety concern for these products was the production of staphylococcal enterotoxins. Improved industrial practices have greatly reduced or eliminated this problem. However, these practices are not adequate to control acid-tolerant bacteria, such as verotoxigenic *E. coli*, which can survive the fermentation and drying process (Glass et al. 1992), as evidenced by outbreaks due both to serotypes O157:H7 (Anon 1995) and O111 (Paton et al. 1996; Desmarchelier 1997).

Use of starter organisms in the fermentation of these meat products allows a greater level of control of the final product. A naturally fermented unheated meat product was the vehicle of infection for an outbreak of

Salmonella serotype Typhimurium infection in the UK when the a_w and pH was insufficient to prevent survival of the organisms present in the raw meat (Cowden et al. 1989).

Spoilage of naturally fermented sausage is due primarily to fungi; *Penicillium* spp. are dominant but species belonging to *Aspergillus* and *Scopulariopsis* are also present (Anderson 1995). Acidulated products are produced by adding acidulants (citric acid, lactic acid, glucono-δ-lactone) to the meat. Because no fermentation is involved, the products require a higher heat treatment than fermented sausages.

DRIED MEATS

Commercial dried meat products, such as beef jerky, include a cooking step that destroys normal vegetative cells and a rapid drying step that reduces the water activity to a level at which microorganisms of concern cannot grow. Thus such products are microbiologically stable at ambient temperature. Some traditionally dried meats such as biltong may include a salting step and a lesser heat process during drying. In such products bacterial numbers, especially micrococci, yeasts, and molds, may be high.

Poultry and poultry products

Poultry production and processing range from small farm or yard operations in developing countries to almost exclusively large-scale, highly integrated, and automated operations in developed countries. Poultry meat is now one of the cheapest forms of meat and consumption has increased dramatically in the past 50 years. It is estimated that 38 million metric tons are produced annually (ICMSF 1998), of which 80 percent is chicken. To meet increased demand, production and processing operations have been integrated and centralized. Intensive production integrates breeding, hatching, rearing, feeding, and slaughtering. The large numbers and close proximity of birds make control of hygiene difficult, and introduction of pathogens into a flock has very serious consequences, although it also provides the opportunity for preventive medicine, efficiencies of sale, and genetic improvements.

In industrialized countries, the microbiological condition of raw poultry at retail sale is a reflection of hygienic measures taken at the breeder farm, at the hatchery, through the growing period, and throughout slaughtering and the subsequent handling and storage.

MICROBIOLOGY AT PRODUCTION

Although several pathogenic bacteria have been associated with outbreaks or sporadic disease caused by poultry products, *Salmonella* spp., *C. jejuni*, and *C. coli* are considered predominant poultry-associated pathogens (Bryan and Doyle 1995), although a thorough examination of raw poultry may yield many other pathogens, including *L. monocytogenes*, *S. aureus*, *E. coli*, and *C. perfringens*. Microbial contamination of the egg can occur during its development in the ovary or later by penetration of the shell after laying. *Salmonella* serotype Enteritidis can infect the ovaries or oviduct of apparently healthy birds, leading to internal contamination of eggs (Coyle and Palmer 1988; Humphrey 1994), but the frequency and extent of such infection are uncertain and the laying of contaminated eggs may be sporadic (Humphrey et al. 1989). Salmonellae may also be present on the egg shell due to fecal contamination and may penetrate the shell during cooling after laying. Chicks and poults may become contaminated from the shell during or after hatching. In contrast, eggs derived from hens that were fecal excreters of *C. jejuni* failed to yield this organism from either the homogenates of yolks and albumen or shell surfaces (Bryan and Doyle 1995). Thus, *C. jejuni* is unlikely to be transmitted by eggs.

Poultry-improvement programs for the genus *Salmonella* identify infected breeder flocks (USDA 1990; EC 1992; Statutory Instrument 1989a, b, 1993a). Infections may be controlled by treatment with antibiotics or by slaughter, particularly if serotype Typhimurium or Enteritidis is identified, and more recently by vaccination programs. Breeder stock should be given feed made free from salmonellae by heating (Williams 1981a, b) or by treatment with organic acids (Hinton and Linton 1988). Other sources of salmonellae, such as rodents and wild birds, should be excluded. New stock should be disease-free and should be quarantined before being mixed with other birds. Contamination of the shell has been reduced by the use of cages and automated feeding systems, belt collection of eggs, and manure removal equipment. Other improvements include in-line washers, mass egg candling, and automated packing equipment (Bell 1995).

The development of the microflora of the live bird is reviewed by Grau (1986) and the origins and composition of the contamination of the carcass by Mead (1980, 1982) and the ICMSF (1998).

Within 24 h of oral inoculation with *C. jejuni* a single chick can contaminate 70–100 percent of fellow chicks held in transport boxes. *C. jejuni* colonizes primarily the lower intestinal tract of chicks, principally the cecum, large intestine, and cloaca. *C. jejuni* are chemotactically attracted to mucin; highly active flagella assist them to move into mucus-filled crypts, where the organisms establish themselves. The colonization of poultry by *C. jejuni* and intervention strategies for prevention of the colonization have been described by Stern (1992).

Salmonellae have been isolated from the yolk sacs of chicks, setters, and chick belts sampled at hatcheries. The cecum is considered the principal site of colonization. Chicks and poults are readily infected with salmonellae from contaminated feeds or drinking water, or by

pecking in contaminated soil or litter; infected chicks may shed as many as 10^8 cfu/g of feces. As they mature, the birds tend to shed fewer salmonellae and fewer birds remain infected unless salmonellae are continuously reintroduced through contaminated feed or other environmental sources (Bryan and Doyle 1995).

Live poultry showing no symptoms of illness may carry and excrete low numbers of salmonellae (symptomless excreters), thereby contaminating the environment. Litter becomes contaminated with droppings, feathers, and soil; with time and use, the water activity, ammonia content, and pH of the litter become unfavorable for the survival of salmonellae.

Transmission of microorganisms between birds continues during transportation from the farm to the slaughtering facilities. Intestinal colonization is the most important factor contributing to carcass contamination. Feed is usually withheld for several hours before transport to reduce the amount of fecal droppings. However, considerable defecation still occurs during transit. Birds stand, walk, and fall on the fecal material present on crates and truck beds, thus allowing fecal bacteria including pathogens to be transferred to the feathers and skin. Stress caused by gathering, transporting, crowding, and holding in crates greatly increases the bacterial load; the levels of *C. jejuni* on unprocessed chicken carcasses increase by 3–4 logs after transportation from the farm (Stern et al. 1995). Cleaning and disinfection of cages and truck beds after each use minimizes the transfer of contamination between flocks.

In countries where birds are killed after purchase by the consumer, the hygienic conditions of preparation may be primitive but the brief time between slaughter and consumption of the cooked product usually prevents most microbiological problems.

Most modern poultry-slaughter operations are largely automated with electrical stunning and mechanical severing of the blood vessels in the neck. Most dressing and processing steps are accomplished with minimal handling. Broilers entering the slaughtering plant are frequently contaminated with *Salmonella* spp., *C. jejuni*, *C. coli*, and *E. coli* (Kotula and Pandya 1995; ICMSF 1998). Dressing procedures are designed to reduce contamination, and controls such as chlorinated rinses of equipment are aimed at minimizing cross-contamination between carcasses.

Carcasses are scalded to facilitate the removal of feathers, the most common method being immersion scalding. Microbes from the exterior surface of the birds and from the intestinal and respiratory tracts are continually released into the scald water. Hot-water sprays, steam, and simultaneous hot-water spray and plucking are alternatives to immersion scalding but are rarely used. Build-up of contamination is prevented by controlled overflow and countercurrent replacement of scald water and by the lethal effects of the high temperature. High scalding temperatures (greater than 60°C) are more effective in eliminating vegetative microorganisms than are the lower temperatures commonly used (50°C), but the lower temperatures are sometimes preferred because they cause less damage to the appearance of the carcass (Slavik et al. 1995).

Plucking (picking) to remove feathers is another process that spreads bacterial contamination between carcasses. Effective cleaning of defeathering machines (pluckers) and the plucking fingers is an important step to prevent transmission of contaminants between carcasses. Spray washing of carcasses after plucking removes only loosely attached contaminating material together with a proportion of the microbial flora, many microbes remaining bound to the surface tissues. Removal of the viscera may lead to further spread of contamination over the carcasses, particularly with intestinal organisms, commonly as a consequence of gut breakage. With time, bacteria become attached more firmly to the skin, so post-evisceration washing should be undertaken as soon as possible and should include washing of both the body cavity and the outer surface of the carcass. Reduction of the levels of bacteria is usually limited to about 90 percent; the remaining bacteria are either entrapped within or adhere to skin and flesh surfaces.

Carcass chilling delays the growth of spoilage bacteria and prevents the growth of food-borne pathogens. Continuous countercurrent immersion chilling, with or without ice, generally decreases microbial numbers on carcasses and minimizes cross-contamination between the carcasses if it is correctly controlled and the water is properly chlorinated. Air chilling using various combinations of temperature, humidity, and time may also be employed. During such dry chilling contact between carcasses is less; however, there is also less dilution of pathogens. Campylobacters, however, are sensitive to drying; therefore, a reduction in the numbers of *C. jejuni* may be expected.

The number of microbes detected on the finished poultry carcass varies with both the site sampled and the method of sampling. Excised skin samples will yield a microflora of approximately 10^3–10^5 aerobic mesophiles/cm, 10^1–10^3 psychrotrophs/cm, and 10^3–10^4 Enterobacteriaceae/cm (Grau 1986; ICMSF 1998). The main causes of spoilage when carcasses are stored in air at approximately 1°C are pseudomonads, *Shewanella putrefaciens*, *Acinetobacter* spp., and *Moraxella* spp. At higher temperatures atypical lactobacilli and *Serratia liquefaciens* (formerly *Enterobacter liquefaciens*) may predominate. *S. putrefaciens* and acinetobacters grow better in leg muscle (pH 6–6.7) than in breast muscle (pH 5.7–5.9), whereas *Pseudomonas* spp. grow well in either. If carcasses are wrapped in oxygen-impermeable films, then *Alteromonas* spp., *B. thermosphacta*, and atypical lactobacilli are the principal causes of spoilage. Atmospheric concentrations of 10–25 percent carbon dioxide delay the growth of pseudomonads and other spoilage

organisms when the product is held below approximately 4°C. The increase in shelf-life is approximately proportional to the concentration of carbon dioxide up to 25 percent, at which point discoloration occurs.

Irradiation of poultry has been extensively investigated with respect to its effects on spoilage and pathogenic bacteria. Treatment of whole eviscerated chickens with 2.5 kGy of γ-rays resulted in an increase in the shelf-life from 10 to 40 days. The same dosage reduces the numbers of salmonellae, campylobacters, and *Y. enterocolitica* by 2.5–4 $\log_{10}$ units. Irradiation is less effective for killing salmonellae on frozen carcasses than on chilled. The US Department of Agriculture issued regulations in 1992 permitting the irradiation of packaged, fresh or frozen poultry and poultry products, including ground and mechanically separated poultry products at a dosage level of 1.5–3.0 kGy (Lee et al. 1996). The UK regulations of 1990 (Statutory Instrument 1990b) permit the sale of specified types of irradiated food (seven types including poultry) where irradiation has taken place under licence. The regulations also specify the limits of overall dose of ionizing radiation which apply.

Eggs and egg products

Since the pioneering study of egg microbiology in 1873 by Gayon, an associate of Louis Pasteur, a number of investigators have shown that the hen's egg is endowed with many chemical and physical defences against microorganisms. The shell and its membranes provide a physical barrier to penetration in addition to possessing bactericidal activity (Board et al. 1994), while the antimicrobial components of the egg white make it an antagonistic medium for microbial growth. The yolk is an excellent medium for bacterial growth; either liquid whole egg or egg yolk permits rapid growth of bacteria if the temperature is appropriate.

Bacterial contamination of eggs can occur at different stages ranging from production to storage, processing, distribution, and preparation (Board and Fuller 1994; ICMSF 1998). Transovarian or 'vertical' transmission takes place when infection occurs during formation of the egg in the hen's ovaries. Horizontal transmission refers to contamination when eggs are exposed to microorganisms that subsequently penetrate the shell (Fajardo et al. 1995). *Salmonella* serotype Enteritidis (*S. enteritidis*) emerged as a transovarian pathogen in 1985 (St Louis et al. 1988) and has caused many egg-related outbreaks of salmonellosis in North America and Europe (Mishu et al. 1991, 1994; ACMSF 1993a, 2001; Humphrey 1994). Phage types (PT) 4, 8, and 13a are the three most frequently isolated phage types of *S. enteritidis*. PT4 causes more severe disease than the other two phage types and during the 1990s essentially displaced the other two phage types in Europe. In the USA the predominant types were PT8 and PT13a, and PT4 did not appear until 1993 (Mason 1994). *S. enteritidis* contamination of eggs may occur by both vertical and horizontal transmission. The frequency of salmonella contamination of shell eggs produced in the UK in 1991 was reported just under 1 percent (de Louvois 1993a, b). Despite extensive and costly measures adopted by the industry to address the problem, this had not improved by 1995 (ACMSF 2001).

The washing of shell eggs does not assure the total removal of bacteria. The temperature of the wash water is not high enough to effect any killing of bacteria, but its pH may affect bacterial growth. Gram-negative bacteria on the egg shell can be resistant to detergents in the wash water; even chlorine rinses of shell eggs may not prevent contamination by salmonellae.

Success in preserving safe and wholesome eggs depends on three steps:

1. preventing spoilage organisms from entering the egg
2. preventing pathogenic bacteria from entering the egg
3. maintaining egg quality by preventing the loss of CO_2 and water.

Refrigeration is the most popular method of preserving egg quality. The low storage temperature retards loss of CO_2 and slows the growth of pathogenic bacteria. Previously the recommended storage temperature for shell eggs in the USA was 13°C. However, *S. enteritidis* grows in eggs stored at 13°C but not at 7°C. Therefore, the 1995 Food Code currently requires the receipt of shell eggs at 5°C (Food Code 1995). The reported decline of infections in the USA (ACMSF 2001) may be explained by the interventions introduced in the egg and or meat/poultry industry (Department of Health and Human Services 1999). In Europe the marketing of eggs is controlled by EC Directives (EC 1989). These allow on-farm storage of eggs for a limited time at ambient temperature not exceeding 18°C before delivery. At retail the directives prohibit storage below 5°C to ensure quality standards are maintained. In the UK, it is recommended that eggs are stored in home refrigeration at less than 8°C (ACMSF 1993b).

Liquid whole egg is a blend of egg albumen and yolk and contains 23–25 percent solids. Liquid egg is used in bakeries, candy makers, and many catering establishments. Contamination of liquid egg products is generally due to contaminants within the shell egg, the cleanliness of the shells on breaking out, or the presence of small egg shell particles that often drop into the liquid. At the time of laying, the egg temperature is above 41°C. The cooling and drying of the moist egg surface, especially the cuticle, and the continued cooling of the contents result in a negative pressure inside the egg. Thus bacterial contaminants are pulled from the surface of the shell through the pores. Shell contaminants therefore make an important contribution to the microbial flora of the liquid egg; washing eggs in water is an effective

method of removing shell contaminants. Spoilage bacteria occurring in liquid eggs are mainly gram-negative rods (*P. fluorescens*, *Alcaligenes bookeri*, *Paracolobacterium intermedium*, *Proteus melanovogenes*, *S. putrefaciens*, *Proteus vulgaris*, *Flavobacterium* spp.). Many *Salmonella* serotypes are associated with egg products. Both *L. monocytogenes* and *Y. enterocolitica* may also be found in liquid eggs (Stadelman 1994).

In the USA and in the European Union, all liquid, frozen, and dried whole egg, yolk, and albumen must be pasteurized or otherwise treated to reduce the number of viable salmonellae to very low levels. The US regulations require that liquid whole egg be heated to at least 60°C and held at that temperature for 3.5 min. The UK regulations specify a heat treatment of not less than 64.4°C for at least 2.5 min or another temperature/time combination that will give the same degree of destruction of vegetative pathogens (Statutory Instrument 1993b; EC 1989). Either temperature–time combination process significantly reduces the number of spoilage bacteria and pathogens without affecting the functional properties of liquid egg. As liquid egg white may have a pH of between 7.6 and 9.3, it should be stabilized by the addition of ammonium sulfate before applying the heating step. Processes using heat and hydrogen peroxide combinations are also acceptable (Baker 1994).

In 1993, a commercially produced mayonnaise was epidemiologically implicated as the source of *E. coli* O157:H7 in an outbreak of bloody diarrhea. However, the evidence suggested that contaminated meat was the more likely source of the organism. Subsequent studies have shown that *E. coli* O157:H7 is more acid-tolerant than other gram-negative enteric bacteria and can survive in refrigerated acidified foods, including mayonnaise. Interestingly, *E. coli* O157:H7 was rapidly inactivated in mayonnaise when it was stored at room temperature (Weagent et al. 1994; Zhao and Doyle 1994; Erickson et al. 1995).

Fish and fish products

The consumption of seafood products has increased dramatically in recent years. This increase has focused greater attention on both the quality and the safety of these products and has led to the development of hazard analysis critical control points (HACCP, see section on New approach to assuring the safety of foods) systems and inspections.

The term 'fish' is used commonly as both a specific term for 'finfish' and also as a generic term covering all edible aquatic and marine finfish, molluscan shellfish, and crustaceans. In this section the individual groups will be referred to by their specific names.

Finfish are generally regarded as more perishable than other high-protein-muscle foods. This high perishability is due primarily to the presence of high concentrations of free nonprotein nitrogenous compounds in fish muscle. These compounds, e.g. ammonia, urea, trimethylamine oxide, creatine, taurine, etc., are utilized actively by bacteria during spoilage, resulting in fishy, ammoniacal smells (Jay 2000). In addition, the perishability of cold-water fish is not effectively reduced by refrigeration because of the preponderance of psychrotrophs in their microflora.

The internal flesh of live, healthy fish is sterile; the natural bacterial flora reside primarily in the outer slime layer of the skin, on the gills, and in the intestinal tract of feeding fish. Bacterial numbers will depend on the temperature of the waters but will range from 10^2 to 10^6 cfu/cm on the skin, from 10^3 to 10^5 cfu/g on the gills, and from very few (nonfeeding fish) to 10^7 cfu/g or greater in the intestines. These initial microflora are directly related to the environment, whereas the total microbial load is subject to seasonal variation. Warm-water fish tend to have a more mesophilic, gram-positive microflora (micrococci, bacilli, coryneforms), whereas cold-water fish harbor predominantly gram-negative psychrotrophs (*Moraxella*, *Acinetobacter*, *Pseudomonas*, *Flavobacterium*, *Vibrio*). Regardless of the initial microflora, spoilage of finfish during iced storage is primarily caused by *Pseudomonas* spp. and *S. putrefaciens*.

The level of bacteria present on a fish is not a reliable indicator of its sensory quality or shelf-life. Gram-negative bacteria are the major causes of fish spoilage. Their metabolism produces the unpleasant odors and flavors associated with fish spoilage. *Shewanella putrefaciens* (previously classified in the genera *Alteromonas* and *Pseudomonas*) is the most important fish-spoilage bacterium in marine fish stored at 0°C; it produces H_2S and causes off-odors. Spoilage bacteria belonging to the family Vibrionaceae are important in spoilage of fish stored at temperatures higher than 0°C (Gram 1992).

The only bacteria that are both pathogens for humans and indigenous members of the normal microflora of the marine environment are *C. botulinum* and various *Vibrio* spp. Other bacterial species may contaminate fish taken from waters subject to human or animal pollution; most of the recognized food-borne pathogens have been isolated from finfish or shellfish.

CRUSTACEANS

Crustacean species of commercial importance include crabs, lobsters, shrimps, and prawns. Crabs and lobsters are generally trapped and transported live to the processing plant. Shrimps and prawns are usually captured by trawlers and iced for transport to the processing plant. As crustaceans may be caught close inshore, a proportion will be from polluted waters and will be contaminated with microorganisms derived from sewage.

Shrimps and prawns are common causes of food-borne illness involving *S. aureus*, *Salmonella* and *Shigella* species and *Vibrio parahaemolyticus*. They are harvested

from coastal waters in many parts of the world and may be captured either by fishing from boats or by hand-netting from the shore. Increasingly they are grown in ponds (aquaculture). The microorganisms present will depend on where the crustacean shellfish are caught. There may be a variety of microbial pathogens originating from untreated sewage, such as *Salmonella* and *Shigella* species, or the organisms that are part of the normal flora of the animal, such as *V. parahaemolyticus* or *Vibrio vulnificus*. Crustaceans are extremely susceptible to microbial deterioration and ideally should be harvested from unpolluted water and cooled rapidly to a temperature of −1 to +2°C. The ice used for chilling should be of good microbiological quality; alternatively clean refrigerated seawater may be used. If water quality is suspect, it should be chlorinated or otherwise treated, but excessive use of chlorine or other biocidal agents should be avoided. On fishing vessels, holds and container boxes should be cleaned thoroughly between catches to prevent a build-up of contamination.

MOLLUSCS

Molluscan shellfish include bivalves, such as oysters, mussels, cockles, clams, and scallops, and gastropods such as whelks and periwinkles. With the exception of some oysters and scallops, which are harvested from deeper waters, most molluscs grow in estuarine and nearshore coastal waters where exposure to fecal contamination is both possible and likely. Clams and cockles are usually dug from the sand; oysters and scallops are either raked or trawled from the seabed; and mussels are hand picked. Oysters and mussels are frequently farmed. They are transported live in the shell, often with little refrigeration. Molluscan shellfish are filter feeders and can concentrate microorganisms from the water in their bodies. Hence the need for depuration in clean water, especially if the mollusc is to be consumed raw.

Vibrio spp. are important pathogens often associated with the consumption of clams and oysters. In 1989, a co-ordinated surveillance for human infections caused by *Vibrio* spp. in four US Gulf Coast states (Alabama, Florida, Louisiana, and Texas) revealed 121 cases of molluscan shellfish associated illness, of which 71 had gastroenteritis, 29 wound infections, and 14 primary septicemia. *Vibrio cholerae* non-O1, *V. hollisae*, *V. alginolyticus*, *V. fluvialis*, *V. parahaemolyticus*, and *V. vulnificus* were isolated from the patients (Levine and Griffin 1993). *V. vulnificus* causes wound infections and primary septicemia with high mortality in susceptible persons, particularly those with impaired liver function. Shellfish, particularly clams and oysters, taken from contaminated waters have also been incriminated as the source of outbreaks of infectious hepatitis A (Bryan 1980) and may serve to transmit other viruses, including caliciviruses, enteroviruses, noroviruses (Norwalk-type viruses), snow mountain agent, and non-A/non-B hepatitis viruses (Cliver 1971, 1988). Noroviruses may be the most frequent cause of shellfish-borne illness.

Toxins have been responsible for a number of seafood-associated outbreaks of illness in the USA, the UK, and elswhere. The principal intoxications having a microbiologial origin include paralytic shellfish poisoning (PSP), diarrhetic shellfish poisoning (DSP), neurotoxic shellfish poisoning (NSP), amnesic shellfish poisoning (ASP) (or domoic acid poisoning), ciguatera, and scombrotoxic (biogenic amine) fish poisoning (Scoging 1997). PSP, DSP, and NSP are caused by toxins produced by dinoflagellates, ASP by a diatom toxin, and all result from the consumption of bivalve molluscs that have been feeding on toxigenic algae, accumulating the toxin in their organs. Ciguatera toxin originates from toxic microalgae that are passed up the marine food chain from herbivorous to carnivorous fish, magnifying the toxin levels. The toxigenic organisms are not usually detectable in the seafood and identification depends on toxin analysis (Scoging 1997). Scombroid poisoning is caused by consumption of fish containing high levels of histamine (and other biogenic amines) resulting from the histidine decarboxylating activity of bacteria multiplying on fish after catching or during the food processing and preparation chain. The toxins are not denatured by cooking or eliminated by cleansing of shellfish in purification tanks. Hence the only available control measure is to prohibit collection of shellfish when, during periods of dinoflagellate blooms, the toxins in the shellfish approach dangerous concentrations.

Vegetables and fruits

Fresh vegetables and fruits are an essential part of the diet of people worldwide. If land is available, families grow their own fruits and vegetables. Otherwise, produce is purchased from local farmers or retail establishments. In developed countries, the production, processing, storage, and distribution of fruits and vegetables are highly integrated and are consolidated in a few commercial companies. This has resulted in year-round availability of such produce; efficient production and processing have also enabled the industry to meet the increased demand from a health- and nutrition-conscious public. However, these integrated practices have given rise to some new public-health problems.

VEGETABLES

Bacterial contamination of vegetables is a public-health concern because of soil microorganisms and the possibility of contamination from water used for irrigation and the various materials, including night soil, used as fertilizers. Several studies have shown that bacteria of public-health concern can be isolated from whole and prepared

vegetables. Control of the quality of plant foods begins at production with suitable geographical location; choice of seed, fertilizers, and pesticides; effective use of irrigation or drainage systems; and crop rotation. In developed countries there is little obvious association between agricultural practices and food-borne illness. The relatively large scale of many agricultural operations results in minimal human or animal contact with crops and constitutes a useful safety factor. Practices such as prolonged cooking and rejection of bruised or rotted foods also minimize the consumption of potentially hazardous material. In developed countries the control measures for quality of plant foods and for minimizing product loss from bruising, browning, wilting, or rot result in foods with minimal microbiological hazards.

The nutrient content of vegetables is suitable for the growth of molds, yeasts, and bacteria (Jay 2000). The number of bacteria on vegetables upon arrival at a processing plant ranges from 10^4 to 10^7/g (ICMSF 1998); number of fungi on fresh vegetables at harvest ranges from 0 to 5×10^5, and at market from 5×10^3 to 2×10^6 (Brackett 1987). Fresh vegetables are inherently susceptible to spoilage because the a_w is above the minimum (0.90) needed to support the growth of most microorganisms, and the pH of most vegetables is within the range allowing multiplication. Washing can remove up to 90 percent of the surface microorganisms, depending on the smoothness of the surface, but those trapped on the vegetable remain and any residual water facilitates their rapid multiplication. Microorganisms multiply faster in cut produce because of the ready availability of nutrients and water. Further handling of the produce increases the likelihood of additional contamination from the handler, work surfaces, or utensils, which may have been contaminated previously by contact with other foods. Most fungal spoilage is caused by the genera *Penicillium*, *Sclerotinia*, *Botrytis*, and *Rhizopus*. A more complete listing is given by the ICMSF (1998). Fungal spoilage of fresh vegetables is considered more an economic than a health threat because few spoilage fungi produce toxic metabolites. Exceptions include aspergilli, penicillia, and *Alternaria*. Stress metabolites that are sometimes produced by plants in response to fungal infections can affect humans, e.g. furanocoumarin compounds, called psoralens, which are produced when *Sclerotinia sclerotiorum* produces 'pink rot' of celery. The effects of these compounds include blisters or lesions of the skin of consumers and those handling the diseased celery.

Bacteria cause a range of spoilage conditions known as rots, spots, blights, and wilts. Soft rots, which occur during transport and storage, are usually caused by coliforms, *Erwinia carotovora*, and certain pseudomonads. Bacteria causing spoilage other than soft rot include corynebacteria, xanthomonads, and pseudomonads (Lund 1983). Soft rot of potatoes by *Clostridium* spp. has also been reported (Lund 1972, 1986). These organisms break down pectins, causing a soft consistency, sometimes with an objectionable odor and a watery appearance.

Storage

Harvested vegetables and fruits continue to respire actively and produce heat. Handling and storage procedures therefore should minimize respiration and water loss and maintain an environment in which cells of the product remain healthy. Rapid chilling is important for leafy vegetables. Correct temperature and humidity control are essential in order to promote wound healing and to minimize spoilage of root crops. A weak link in the distribution chain for fruits and vegetables is the use of unsuitable containers or packaging material (e.g. large sacks, rough wooden boxes, bamboo baskets), which can result in crushing, bruising, and puncturing of the product. Long journeys, hot weather, unventilated trucks, heavy loads, and unpaved roads in developing countries are responsible for huge losses of fruit and vegetable harvest (Ryall and Lipton 1979; FAO 1981; Proctor et al. 1981).

The only means of control of spoilage microorganisms is by strict sanitation of equipment and control of the temperature, relative humidity, and gas composition of the atmosphere in which the raw vegetable is stored. Further examples of vegetable spoilage are given in Dennis (1987), ICMSF (1998), and Jay (2000).

Modified-atmosphere packaging or vacuum packaging is used to suppress the proliferation of aerobic spoilage microorganisms on vegetables. In addition, these processes reduce the rate of oxidative deterioration, enzymatic degradation, and water loss. Modified-atmosphere or vacuum packaging is used to market fresh-cut packaged vegetables including cabbage, lettuce, onions, green and red peppers, carrots, cauliflower, broccoli, and other leafy salad vegetables. Spoilage of ready-to-use salads is frequently caused by pectinolytic pseudomonads such as *Pseudomonas marginalis*.

Freezing is a preferred means of preserving vegetables, since both the organoleptic and the nutritional quality are better retained than by other processes. Before freezing vegetables it is normal practice to blanch, usually at 86–98°C for several minutes, to inactivate plant enzymes, thereby stabilizing the product during subsequent frozen storage. Blanching commonly reduces the microbial load 10^3–10^5 times. In most frozen vegetables, lactic acid bacteria are numerically dominant, although micrococci and gram-positive and gram-negative rods, including coliforms, comprise a considerable proportion of the total microflora of certain products. Microbial spoilage of frozen vegetables is rare, and they are rarely involved in food-borne illness because nonspore-forming pathogens do not survive

blanching and most frozen vegetables are cooked before consumption.

Dried vegetables are shelf-stable and are rarely involved in food-borne illness although they can be a source of organisms, particularly spores of clostridia and bacilli, when rehydrated or when added in the dried form to other dishes. Modified atmospheres have been used to control fungal spoilage of vegetables, with mixed results. An increased carbon dioxide concentration is fungistatic for many fungi, including *Candida albicans*, *Botrytis cinerea*, *Botrytis parasiticus*, *Penicillium* spp., *Mucor*, and *Aureobasidium pullulans*, but there are examples of some vegetables being either more or less sensitive to increased concentrations of carbon dioxide, or off flavors developing due to the different gases used for preservation.

Vegetables can be contaminated with pathogenic microorganisms during growth, at harvesting, post-harvesting handling and storage, and distribution. Beuchat (1996) has published a comprehensive review on this subject. Food-borne disease outbreaks of bacterial origin are associated more frequently with vegetables than fruits. Among the bacterial pathogens of greatest concern in vegetables are *Shigella* spp., salmonellae, enterotoxigenic, enteropathogenic, enteroinvasive, and enterohemorrhagic *E. coli*, *Campylobacter* spp., *Y. enterocolitica*, *L. monocytogenes*, *Aeromonas* spp., *V. cholerae*, *S. aureus*, *Bacillus cereus*, *C. perfringens*, and *C. botulinum*.

Several large outbreaks of shigellosis have been traced to contaminated vegetables such as shredded or cut lettuce and fresh green onions. With the current popularity of fresh-cut packaged produce, there is a potential for causing large, geographically widespread outbreaks. *Shigella* spp. can survive on vegetables for several months at ambient and refrigerator temperatures.

Vegetables implicated as vehicles of *Salmonella* spp. in food-borne disease outbreaks include raw tomatoes and bean sprouts. *Salmonella* spp. can grow on raw tomatoes (pH 4.0) at 20–30°C. *L. monocytogenes* was established as a food-borne pathogen after a large outbreak of listeriosis in Nova Scotia in 1981 in which contaminated coleslaw was implicated (Schlech et al. 1983). The cabbage that was used to prepare the coleslaw had been grown on fields that were fertilized with contaminated sheep manure. In addition, the cabbage was stored at refrigeration temperatures over winter; this probably allowed the psychrotrophic pathogen to multiply. *L. monocytogenes* is a common natural contaminant of raw vegetables. The ability of the organism to survive and multiply at low temperatures makes it a difficult organism to control in the cool, moist environments of food-processing establishments. The organism can also exist in biofilms, which impede the process of cleaning and disinfection. The cut surfaces and exudate from some chopped vegetables, such as lettuce and cabbage, included in ready-prepared salads, both prepacked and from delicatessen counters, may provide an ideal substrate for the growth of *L. monocytogenes* (Beuchat and Brackett 1990a). The juice of other vegetables, for example carrots, may be inhibitory (Beuchat and Brackett 1990b). Many cases of travelers' diarrhea are attributed to enterotoxigenic *E. coli* acquired from contaminated salads eaten at restaurants. Salad-bar vegetables and lettuce have been implicated in instances of infection with *E.coli* O157:H7.

Vegetables sold in modified-atmosphere packages may pose a threat of botulism. *C. botulinum* type A spores have been isolated from shredded cabbage, chopped green pepper, and a salad mix. There is likely to be a hazard only if they have been prepared or stored under conditions that will lead to spore germination, cell multiplication, and toxin production. The presence of normal spoilage microflora in vegetables packaged under modified atmosphere may actually prevent the growth of *C. botulinum* and production of toxin. Packaging under modified atmosphere does not prevent the growth of *E. coli* O157:H7 on shredded lettuce or sliced cucumbers.

FRUITS

Losses in fresh-fruit harvests due to rots and other defects are usually the result of mold growth. Some molds are able to invade and infect the intact healthy tissue, whereas others can become established only after the fruit has been infected by a pathogen or has been damaged. Several diseases are named after the causative mould (e.g. *Alternaria*, *Botrytis*, and *Fusarium* rots) and others are derived from the appearance of the infected fruit (e.g. brown rot, stem-end rot). In some cases diseases of different fruits may have the same name despite the involvement of different molds (e.g. black rot is caused by *Physalospora obtusa* in apples and by *Alternaria citri* in oranges). The market diseases of fruits, and their causative fungi, are tabulated by the ICMSF (1998). Yeast spoilage of fresh fruits is usually from the fermentative action of, for example, *Hanseniaspora valbyensis*, *Candida* spp., *Candida (Torulopsis) stellata*, *Pichia kluyveri*, and *Kloeckera apiculata*.

At the orchard or vineyard pruning, certain cultural practices and application of fungicides are the main means by which infection and spoilage prior to harvest are minimized. After harvesting at optimum maturity, fruit should be handled gently to prevent physical injury and fruit-contact surfaces should be cleaned regularly and treated to destroy fungal spores. Moldy or bruised fruits are removed during sorting and grading. Fruit may be treated with hot water or with permitted fungicides to control, for example, *Phomopsis*, *Diplodia*, *Penicillium*, and *Botrytis* (Salunkhe and Desai 1984).

Storage

Fruits are stored cooled but at temperatures that do not cause chill injury. The concentration of carbon dioxide in the atmosphere may be increased to inhibit *Alternaria*, *Botrytis*, and *Rhizopus* spp. Fruit products can be preserved by heating to approximately 80–90°C because most aciduric microbes are relatively sensitive to heating. Spoilage of canned soft drinks has occurred because ascospores of *Saccharomyces cerevisiae* or spores of *Kluyveromyces marxianus* survived the heat process. Spoilage of canned-fruit products has occurred because ascospores survived the heating process, e.g. *Penicillium vermiculatum* and *Byssochlamys* (Splittstoesser 1987).

Freezing is often used to preserve fruits and fruit products and results in some reduction in microbial numbers. Growth of yeasts and molds does not occur if temperatures are maintained below −18°C, but exposure to automatic defrost cycles is undesirable in the long term because some multiplication may occur.

Reduction of the water activity is a common means of fruit preservation, either by natural exposure to the sun or by a controlled dehydration procedure. Fungal spoilage of dried fruit does not occur when the water content is below 25 percent. Some high-moisture dried fruits contain 30–35 percent moisture and are therefore heated or treated with potassium sorbate to prevent mold growth. Many fruits are treated with sulfite before drying to prevent browning and this destroys a high proportion of the contaminating microbes. Yeasts and molds able to grow on dried fruit include *Zygosaccharomyces bisporus*, *Zygosaccharomyces rouxii*, *Hanseniaspora*, *Candida*, *Penicillium* spp., *Aspergillus glaucus*, and *Aspergillus niger*. *Monascus bisporus* is one of the most xerotolerant molds and has caused spoilage of dried prunes (Splittstoesser 1987). The relationship between water activity and fungal growth is reviewed thoroughly by Corry (1987).

Pathogenic bacteria are not normally associated with fruit; however they may be present due to fecal contamination. Survival times of enteric pathogens on fruits will depend on pH and temperature. On high-acid fruits, e.g. lemons, it will be shorter than on low-acid types, such as melons. Growth is more likely to occur on cut or damaged surfaces.

Sliced fresh fruits support the growth of *Shigella* spp. and thus may serve as the vehicle of infection. Several outbreaks of salmonellosis have been associated with fresh fruits, particularly raw tomatoes and melons. *Salmonella* serotypes Oranienburg and Javiana have caused outbreaks associated with the consumption of contaminated watermelons; serotypes Chester and Poona have been linked with cantaloupes. Organisms can enter either through fissures or cracks in the fruit surface or via the blade or other implement used to slice the fruit. Outbreaks of *E.coli* O157:H7 were attributed to unfermented apple juice, orange juice, and cantaloupe (ICMSF 1998).

CANNED FRUIT AND VEGETABLE PRODUCTS

Preservation by canning is exploited to increase the shelf-life and availability of fruit and vegetables. The heat processing of these products and the importance of pH are discussed thoroughly elsewhere (Hersom and Hulland 1980; Lund 1986). Most vegetables intended for canning fall into the category of foods known as 'low-acid' because their pH is above 4.6. Low-acid foods must be heated sufficiently to destroy the spores of *C. botulinum*, which are inevitable contaminants of agricultural products, including vegetables. The canning process is a good example of where a high margin of safety is achieved by control of the process rather than by microbiological tests on the raw material and final product. The critical control points in the process, i.e. initial microbial contamination, time between filling and processing, cleanliness of equipment, heat process, cooling cycle and disinfection of cooling water, maintenance of container integrity by seam or seal control, and appropriate handling are outlined in ICMSF (1988). Leaker spoilage of canned vegetables is usually characterized by the presence of a mixture of microbial types, mainly bacteria, while with spoilage due to underprocessing there is often only one species present.

Canned vegetables that have been heat processed to commercial sterility may still contain viable spores that are unable to grow under the normal temperature of storage of the product, e.g. thermophilic spores of *B. stearothermophilus* and *B. coagulans*, which cause flat sour spoilage with production of acid but not gas. Thermophilic anaerobic spoilage may be caused by obligately thermophilic spore-forming anaerobes, such as *Clostridium thermosaccharolyticum*, which forms large quantities of hydrogen and carbon dioxide, or *Desulfotomaculum nigrificans*, which produces hydrogen sulfide, often with blackening of the food if iron is present. Thermophilic spoilage usually occurs after improper cooling of heat-processed vegetables (Hersom and Hulland 1980; Lund 1986; Dennis 1987; ICMSF 1988, 1998).

Cereals, nuts and seeds, and herbs and spices

Cereals are the main staple diet of a large proportion of the world's population, the main ones being wheat, maize, oats, rye, rice, barley, millet, and sorghum. They may be eaten directly after cooking, principally rice, and sometimes maize, or they may be converted into flours for further processing by baking into breads and biscuits or molding into doughs for pasta or noodles. They may be fermented as gruels, manufactured into western-style

cereal products and eaten as breakfast foods, or fermented into beers and wines. The principal microorganisms of concern are fungi and spore-forming bacteria.

The microbiology of cereals is summarized by Pitt and Hocking (1986) and considered in greater detail in ICMSF (1998). Cereals are of near-neutral pH and provide good nutrition for bacteria. Microbial activity is controlled by drying the harvested cereals to a sufficiently low a_w (below 0.70) at which bacteria are unable to multiply, and growth of molds is largely prevented in temperate zones. At the humidity levels common in tropical countries, mold growth is a serious problem. Historically, the molds able to spoil cereals have been grouped into 'field' and 'storage' fungi, but some (e.g. *Aspergillus flavus*) grow in both situations. Field fungi are plant pathogens that invade the crop as a consequence of a combination of favorable circumstances. Particular molds may cause problems in one geographical area, but not in another. For example in Japan an important disease of wheat and barley, (red mold disease) is caused by *Fusarium* spp., predominantly *Fusarium graminearum*, whereas in Australia *Fusarium* spp. appear to cause little problem in wheat, probably due to the drier climate.

Fungi occurring commonly on wheat, barley, and oats in Scotland and England include *Alternaria*, *Cladosporium*, *Epicoccum*, and *Penicillium* spp., while in Egypt wheat carries mainly *Aspergillus* and *Penicillium*, together with *Alternaria*, *Cladosporium*, and *Fusarium*, and barley mainly *Aspergillus* and *Penicillium*, together with *Rhizopus*, *Alternaria*, *Fusarium*, and *Drechslera* (Pitt and Hocking 1986).

Bacteria generally found on cereals are from the Pseudomonadaceae, Micrococcaceae, Lactobacillaceae, and Bacillaceae. The level of fecal contamination will be low in field grains unless there is considerable animal activity. Groups that are nearly always present include psychrotrophic bacteria (10^4 to $>10^7$ cfu/g), actinomycetes (up to $>10^6$ cfu/g), and aerobic sporing bacteria (10^0 to 10^5 cfu/g).

WHEAT

Wheat grows best in fairly dry and mild climates. After harvesting, it is dried and stored and may be transported long distances before final milling. Before consumption, milled wheat is cooked or baked. Spoilage by bacteria is not usually a problem because of the relatively low a_w, but wheat may act as a passive carrier for bacterial pathogens (ICMSF 1998). Some that are part of the normal flora such as *C. perfringens*, *B. cereus* and other *Bacillus* spp. can, under the right set of conditions, become harmful to man when consumed in a final cereal-based dish. Mold growth, spoilage, and the possible presence of mycotoxins are more serious hazards. Under particular weather conditions mycotoxins can be produced while the wheat is growing (Saito and Ohtsubo 1974; Ichinoe et al. 1983) or during storage if the a_w becomes sufficiently high.

Microbiology at production

The diverse surface microflora of wheat in the field does no damage. The grain may, however, be infected by *F. graminearum* to produce wheat scab, red mold disease, or fusarium head blight. Perithecia of *Gibberella zeae* (the perfect stage) maturing in the field liberate ascospores into the air, which infect wheat at the heading stage. Under high relative humidity and low temperatures *F. graminearum* grows and may produce trichothecenes (nivalenol or deoxynivalenol) and zearalenone (Saito and Ohtsubo 1974; Ichinoe et al. 1983; Hagler et al. 1984). There are unresolved geographical differences in the occurrence of trichothecenes, perhaps related to which strains of *Fusarium* occur (Osborne and Willis 1984). *A. flavus* and *A. parasiticus* are common contaminants of certain grains.

The crop is harvested as soon as possible after maturity, before rain can damage the grain (e.g. by causing sprouting). In a single operation, combine harvesters reap, thresh, clean, and load the wheat kernels into trucks for transport to storage. The rate and extent of subsequent drying of the crop depend on the moisture content at harvest (15–22 percent). It is important to harvest mature grain of known moisture content in dry weather without grain breakage and to separate kernels from hull and straw.

The moisture content of harvested wheat may be as high as 22 percent (a_w approximately 0.95), with the temperature reaching nearly 40°C. The grain must then be dried. Also it may need cooling in order to prevent spoilage and mold growth, to lower the respiration rate of the wheat, and to prevent overheating and damage of the grain. Wheat is dried initially to about 13 percent moisture (Zeleny 1971), to an a_w of less than 0.70, and later to 11–12 percent for long-term storage (ICMSF 1998). The higher the moisture content of the grain, the lower the air temperature must be, to prevent heat damage (Kent 1966).

Storage

After drying and before primary storage, wheat is cleaned by screening and aspiration to remove dust, broken and light grain, and foreign material. Broken grain is more susceptible to mold and insect attack (Williams 1983).

When grain is moved from primary storage to long-term storage in terminal elevators by truck or railcar, the vehicles are sources of insects or storage molds (Williams 1983). They may also be a source of contamination by salmonellae if the previous cargo was animals, meat scraps, or meat or fish meal (ICMSF 1998).

Cleaning and fumigation are necessary to keep transport vehicles clean and insect-free. Grain must be protected from rain. On grains at harvest time, mold propagules range from a few to 10^5/g and bacteria from 10^3 to 10^6/g. The bacteria are usually from the families Pseudomonadaceae, Micrococcaceae, Lactobacillaceae, and Bacillaceae. Indicators of fecal pollution are rare unless there has been animal access to fields. The presence of *Bacillus subtilis* and *B. cereus* has been demonstrated and other bacterial spores from the soil should be expected (e.g. *C. botulinum*, *C. perfringens*). Actinomycetes commonly exceed 10^6/g and psychrotrophs 10^4/g. Yeasts occur but do not cause problems during storage. During artificial drying, the temperatures achieved (40–80°C) destroy most mold spores. Sun drying is less effective in this respect.

Flour may be contaminated with spores of *B. subtilis* and *Bacillus licheniformis*, which can give rise to 'ropey' bread particularly if the preservatives commonly added in commercial bakeries are omitted. There is evidence associating large numbers of bacilli other than *B. cereus* with food-borne illness, especially in relation to foods with a flour-based sauce or encased in pastry (Kramer and Gilbert 1989).

RICE

Unlike wheat, rice (*Oryza sativa*) crops are largely grown in relatively small production units without great benefit of mechanization. Also, there is often much human and animal contact with the crop. However, salmonellae and other vegetative pathogens from such sources should be destroyed by the cooking process. Rice is often harvested and stored under hot, humid conditions that increase the risk of fungal attack and present a significant hazard from mycotoxins and spoilage losses. As the a_w is low, bacterial spoilage is rarely a problem. Spores of *B. cereus* survive cooking and have caused food-borne illness (Kramer and Gilbert 1989). The illness that has been recognized as usually associated with the consumption of rice contaminated with *B. cereus* has a rapid onset (1–5 h); the predominant symptoms are nausea, vomiting and malaise and are referred to as the 'emetic syndrome;' occasionally diarrhea may occur. Approximately 95 percent of 'emetic syndrome' episodes have been associated with the consumption of Cantonese-style cooked rice served by Chinese restaurants usually as take-away meals (Kramer and Gilbert 1989). The restaurants store cooked rice for reheating on demand at room temperature for long periods of time. There is a reluctance to store cooked rice in the refrigerator because the grains become sticky and clump together. Heat-resistant spores of *B. cereus* survive the initial cooking period and, during subsequent storage in the warm kitchen, germinate and multiply rapidly and produce toxin. The emetic toxin is extremely heat-resistant (Melling and Capel 1978) and will not be inactivated by the rapid cooking before consumption.

Fungi can invade rice in the field and spoil the developing grain (Fazli and Schroeder 1966; Bhat et al. 1982), while other fungi (storage fungi) attack the rice during drying and storage (Mallick and Nandi 1981; Mossman 1983). A variety of mycotoxins have been found in rice (Jarvis 1976; ICMSF 1998). It is crucial to reduce the a_w of rice quickly to approximately 0.65 to prevent mold growth and to maintain it at that level during storage even in unfavorable climates. Molds can penetrate the endosperm and discolor the kernels, but most mold growth and aflatoxin formation occurs in the bran layers that are removed during milling to produce white rice (Schroeder et al. 1968). Milling also tends to break moldy kernels, which can then be removed, thereby improving the microbial quality of the rice (Ilag and Juliano 1982).

Crop losses caused by plant diseases and insect infestations can be reduced by the planting of resistant varieties and by the application of insecticides (Mikkelsen and DeDatta 1980). Provision of adequate drying and storage facilities for crops harvested in the wet season is critically important (Greeley 1983; Mossman 1983).

Microbiology at production

Rice is harvested when the moisture content is 18–23 percent (DeDatta 1981). Delaying harvest increases field losses (shattering and lodging) and causes subsequent milling losses due to sun-cracking (Chandler 1979; Mikkelsen and DeDatta 1980). Early harvesting gives a more moist grain, which is difficult to hand-thresh and requires more drying.

In traditional tropical operations, rice stalks are pulled out by hand, bundled into sheaves for prethreshing drying, or threshed immediately (Mossman 1983). Manual harvesting causes less damage to the paddy, results in fewer weeds being incorporated into the crop, and allows the gathering of a higher percentage of mature grain. However, the longer the grain is left in the field for prethreshing drying, the greater the risk of cracking and attack by insect molds (Hall 1970). Drying is the most important step in production; if not undertaken or if delayed, the whole crop can spoil. Nevertheless, improper drying can cause grain breakage, partial spoilage, or spoilage losses in storage.

Most rice is sun-dried, and if done correctly this reduces the microbial population (Kuthubutheen 1984). The usual procedure in the tropics is to spread rice on a drying floor exposed to the sun for several days until the moisture level is 14–16 percent (a_w approximately 0.76–0.84). However, at this moisture content, rice cannot be stored safely so further drying during storage is needed. Traditional crops are harvested in the dry season at the time of maximum sun, but this process is often inadequate with increased yields and newer rice varieties that

mature during the wet season. Artificial drying is then necessary, enabling harvests to be dried more uniformly with less loss from grain cracking, and to safe moisture levels (<13 percent moisture or a_w <0.70) regardless of the vagaries of the weather.

Storage

Significant losses can occur during storage if rice is not protected from rodents and insects, or if it is not dry enough to prevent mold growth. Mold attack is exacerbated by the high temperatures and humidities of tropical areas. At the start of storage, up to 85 percent of paddy rice kernels may be internally infected with field molds. During storage, field molds gradually disappear or are replaced by storage fungi (Mallick and Nandi 1981; Kuthubutheen 1984). The type and extent of growth of storage fungi depend on the initial load, temperature, a_w or relative humidity, and time (ICMSF 1998). Paddy rice can be safely stored at 30°C with a constant moisture content of 12.5 percent (a_w 0.67) for 12 months with no fungal growth (Mallick and Nandi 1981). A moisture content of 14.3–14.5 percent (a_w approximately 0.79) produces significant mold growth and deterioration within a few months.

Storage containers such as sacks or baskets give little protection from rodents or insects and may be a source of eggs, larvae, and mold spores (Williams 1983). Some modern rice varieties have thinner husks than traditional cultivars and are more susceptible to insect attack (Greeley 1983). Storage in bins or solid-walled containers provides protection from ingress of rodents, insects, and external moisture from rain or high humidity. However, failure to dry paddy rice to near 12 percent moisture (a_w 0.65) before, or soon after, bin storage causes considerable crop loss. Since rice insulates well, temperature gradients within the bin are readily established and lead to condensation and raised moisture contents in the cooler regions. The resultant increased metabolic activity and mold growth generate heat, carbon dioxide, and more water, resulting in 'hot spots,' which spread upwards and outwards. Bins made of metal are particularly susceptible to temperature gradients resulting from fluctuations in external temperatures.

Insect infestation is controlled by treating sacks, storage areas, and stocks of stored rice with insecticides or fumigants, and by keeping storage areas free of dust, fines, and spilt rice. Paddy rice is not generally transported long distances but transportation should be regarded as an extension of storage, with the same principles of preventing exposure to rain, dew, insects, and rodents.

Milling can improve the microbiological quality of rice. Much of the bacterial and mold contamination and aflatoxin, if present, is on the husk and in the surface layers of the kernel and will be removed by milling in the husk and bran fractions (Ilag and Juliano 1982). Grain heavily infested with mold will also break more readily during milling, yielding discolored, broken rice that is separated in the broken-grain fraction. Much dust is generated during milling; it may absorb enough moisture to allow microbial growth and can be a source of insects. It is essential that dust is controlled by regular sweeping, vacuuming, or aspiration.

The absence of husk makes milled rice more susceptible to insect attack. During storage it must be protected from insects, rodents, and increases in moisture content. Thus the same principles of control apply to milled rice as for paddy. Brown rice may also go rancid as a result of scratches in the bran, allowing lipases access to oils within it (Mossman 1983), possibly because of the presence and activity of a wide range of lipolytic bacteria and molds (DeLucca et al. 1978).

NUTS AND SEEDS

Nuts are dry, one-seeded fruits that are usually enclosed in a rigid outer casing or shell. They mostly grow on shrubs or trees (tree nuts) and include almonds, hazelnuts, pistachios, Brazil nuts, pecans, coconuts, and macadamia nuts. The peanut or groundnut is the only major nut that is a legume, but it tends to be grouped together with tree nuts.

Oilseeds from a range of botanical families are grown primarily for oil production and include palm nuts, rapeseed, sesame, sunflower, safflower, cottonseed, cacao seeds, and maize.

Many types of leguminous seeds are dried, such as a wide variety of beans and also soybeans.

The shells of nuts present an effective barrier to entry of bacteria during growth, and after natural drying the low a_w of most nuts restricts bacterial spoilage or toxin production. Bacterial contamination can occur after harvest, e.g. coconut flesh with salmonellae, with resultant concern over products with high a_w to which nuts are added. The high oil content of nuts and oilseeds results in high susceptibility to attack by lipolytic bacteria and spoilage fungi and possible mycotoxin production. Dried legumes, apart from soybeans, are low in oils so microbiologically are similar to cereals.

Microbiology at production

Tree nuts are usually dried in situ before harvesting. Coconuts are pierced or broken, drained of water, and the kernels cut into slices and sun dried. They may be further shredded as desiccated coconut. Peanuts are pulled from the ground and dried at least partially before threshing. There are few data on the microflora of nuts in the field. The shells provide a strong, protective barrier and tree nuts are essentially sterile before harvest apart from possible systemic fungal infection from the tree. Limited data on peanuts suggest that the flora is mainly field fungi, with *Fusarium* spp., *Lasio-*

diplodia theobromae, and *Macrophomina phaseolina* being dominant (MacDonald 1970).

Primary processing of nuts, seeds, and legumes usually involves natural drying. If there is good sun-drying, the initial microflora may be reduced, but if conditions are adverse, the mycoflora may increase in both kind and numbers and there may be mycotoxin formation. The bacterial flora of raw commodities, as would be expected, reflects the growing and harvesting environment and contamination from soil, equipment, etc. The fungal flora isolated from copra, cashew nuts, peanuts, and dried legumes are listed by the ICMSF (1998).

Storage

Stored dried nuts are very susceptible to spoilage because slight increases in moisture content lead to sharp rises in a_w due to the low levels of soluble carbohydrate and high lipid levels. These increases may be due to uneven storage temperatures; therefore, refrigerated storage is widely used to retard the development of rancidity. Increases in moisture may also lead to growth of spoilage fungi and mycotoxin production. The opening and cutting of coconuts allows contamination with bacteria and also many species of fungi.

A variety of bacteria have been isolated from nuts with damaged cells or contaminated with soil (King et al. 1970) including species of *Bacillus*, *Brevibacterium*, *Streptococcus*, and *Xanthomonas*, as well as *E. coli*. There may also be contamination with bacterial pathogens from animals. Contamination of hazelnuts with *C. botulinum* led to human cases of botulism from yogurt containing inadequately processed hazelnut puree (O'Mahoney et al. 1990). The principal problem with nuts and oilseeds lies with the potential for production of mycotoxins, notably aflatoxins. Peanuts, maize, and cottonseed are the three crops of greatest economic importance affected.

Salmonella has frequently been isolated from desiccated coconut (Gilbert 1982) and has been traced to unhygienic preparation at collection centers at the farms. The salmonella problem has largely been overcome as a result of the hygiene controls that have been implemented. However, a large outbreak of *Salmonella* serotype Java infection traced to a single batch of desiccated coconut was reported in the UK in 1998–99 (PHLS Communicable Disease Surveillance Centre 1999).

The most important step from the microbiological viewpoint in the further processing of nuts is roasting, which results in a large reduction in numbers and types of organisms including enteric pathogens. Control of mycotoxins in nut products consists essentially of control of the raw material or primary processing stages. Sorting and diverting discolored, rejected nuts is an important commonly used means to reduce mycotoxins to acceptable levels in finished products. End-product testing for mycotoxins is widely practiced.

HERBS AND SPICES

Spices are any of a variety of aromatic plant products used to season, flavor, or impart an aroma to foods. They may be fruits (peppers, allspice, coriander), arils (mace), flower buds (cloves), rhizomes (ginger), barks (cassia, cinnamon), or seeds (nutmeg, fenugreek, mustard, caraway, celery, and aniseed). Herbs are generally the leafy parts of soft-stemmed plants (oregano, marjoram, basil, curry leaves, mint, rosemary, and parsley) (ICMSF 1998).

Spices are of microbiological interest for a number of reasons:

- Antimicrobial activity and preservative properties. This activity, due to the essential oils, is of little significance in food preservation. Levels are generally too low to prevent microbial growth but can sometimes augment other microbial activities or act synergistically. Spices containing the most inhibitory of essential oils include cloves, thyme, oregano, cinnamon, allspice, cumin, and caraway. Yeasts are more readily inhibited than bacteria and the gram-positive bacteria are more sensitive than the gram-negative. The activity of a range of essential oils is listed by the ICMSF (1998).
- Stimulation of microbial metabolism.
- Tendency to go moldy at improper humidity and temperature.
- Contain large numbers of microorganisms that may cause spoilage or disease when introduced into foods.

Spices and herbs contain the organisms that are common to the soil and plants in which they are grown and that will survive the drying process. Other sources of contamination include dust, insects, fecal material from birds and rodents, and possibly water. Microbial counts will vary widely depending on original microbial load, opportunity for growth, subsequent die-off, stage of storage, origin of product, etc. Most of the microbial flora consists of aerobic mesophilic sporing bacilli originating from the soil as spores due to their ability to survive the drying process, most commonly *B. subtilis*, *B. licheniformis*, *B. megaterium*, *B. pumilus*, *B. brevis*, *B. polymyxa*, and *B. cereus*. A wide variety of nonsporing organisms may be found including coliforms, *E. coli*, fecal streptococci, and, rarely, staphylococci and lactic acid bacteria. The main components of the mold flora tend to be the *Aspergillus glaucus* group, *A. niger*, and *Penicillium* spp.

As the different spices vary widely in form they require diverse harvesting and post-harvesting methods; these will have a variable effect on their microbial content. The most important consideration is to dry the products rapidly to prevent spoilage while maintaining

their desirable characteristics. ICMSF (1998) gives examples of some harvest and post-harvest treatments.

Spoilage of herbs and spices is mainly by molds, chiefly *Aspergillus* spp.; bacterial spoilage is rare. Insect infestation may aid the transfer of mold spores. However, other foods may be spoiled by the addition of herbs and spices bearing large numbers of bacterial spores; the degree of spoilage will depend on the amount of further processing or heat treatment that the final product receives.

Some of the spore-forming bacteria found in herbs and spices are capable of causing gastroenteritis (*B. cereus*, *B. subtilis*, *B. licheniformis*) (Kramer and Gilbert 1989). *C. perfringens* may also be present. As these spores will survive cooking temperatures, spices harboring these organisms must be considered as a potential health hazard if the foods to which the spices have been added are not properly prepared and handled. Salmonellae have also been found in a variety of spices and have been the source of a number of food-borne outbreaks, for example in black and white pepper and paprika. Aflatoxins have also been found.

NEW APPROACH TO ASSURING THE SAFETY OF FOODS

Food is essential to sustain life. People expect safe foods and expect their food supply to be protected and the safety and wholesomeness assured by governments. These expectations are the basis for food laws and food regulations, the inspection programs that monitor compliance with the laws and regulations, and the judicial system that punishes those who violate the laws. Until recently, governments took the responsibility for inspections of foods, food-processing establishments, and their environment. In several countries, government inspectors are assigned to meat, fish, and poultry processing plants. Inspectors of the US Food and Drug Administration (FDA) perform unannounced inspections of packaged or canned food-processing plants and examine finished product to monitor compliance; similar policies exist in other countries.

Currently the approach to assuring the safety of the food supply being implemented in the USA and several other developed countries is the HACCP system, a preventive approach designed in the 1950s to assure the safety of foods in manned space flights (Bernard 1997). The system goes beyond the limited effectiveness of sampling and examining finished goods.

HACCP is a systematic approach to the assurance of safety in food production. It consists of a number of sequential steps:

1. Hazard analysis.
2. Determination of critical control points (CCP).
3. Determination of the critical limits to be met at each identified CCP.
4. Establishment of procedures to monitor critical limits.
5. Establishment of corrective action to be taken when a deviation is identified by the monitoring.
6. Implementation of effective record-keeping-systems.

The concept adopted is based on understanding how a product becomes unsafe. Then control measures can be developed to prevent or detect such failures and keep them from reaching the consumer.

Hazard analysis is an assessment of risks associated with all aspects of food production from growing in the fields to consumption. The hazards may be physical, chemical, or biological. The biological hazard category includes bacterial, viral, fungal, and parasite contamination. Pathogenic bacteria are classified on the basis of the severity of risk: *C. botulinum*, *Salmonella* serotype Typhi, *E. coli* O157:H7, and *V. cholerae* are classified as severe hazards; *L. monocytogenes* and *Salmonella* serotypes other than Typhi are classified as moderate hazards with potential for extensive spread; *B. cereus* and *C. perfringens* are classified as moderate hazards with limited potential for spread. The hazard analysis also includes the ranking of food and its raw materials or ingredients according to six hazard characteristics followed by assigning a risk category to the food and its raw materials based on the hazard rankings.

Critical control point determination is required to control the previously identified hazards. A CCP is defined as any point or procedure in a specific food production system where a loss of control may result in an unacceptable risk.

Critical limits must be established that must be met at each identified CCP. For example, the thermal treatment in a retort in the production of low-acid canned foods is a CCP. The components of the CCP include pressure of the retort, retort temperature and time the food is held at the retort temperature.

Monitoring procedures must be established and also the corrective actions to be taken when a deviation is identified by monitoring critical components of a CCP. Implementation of *effective record-keeping systems* that document the HACCP plan is also an essential requirement of HACCP.

HACCP-based regulations were published first in the USA for low-acid foods in hermetically sealed containers and then later for smoked fish products. In February 1995, the Food Safety and Inspection Service of the United States Department of Agriculture (USDA) published proposed regulations (FSIS 1995). These essentially overhaul the meat and poultry inspection system and change it from a reactive, federal inspection-based approach to a proactive HACCP approach in which the manufacturer or processor assumes greater responsibility for food safety. Both the US FDA and the USDA have published final regulations mandating the development and implementation of

HACCP plans to cover a variety of domestic and imported foods (Bernard 1997).

The US initiatives have been paralleled in other countries. The European Union (EU) has adopted a number of product-specific directives that require specific foods introduced into commerce within EU countries to be produced in accordance with HACCP principles (e.g. fishery products, milk and milk-based products, meat products). In addition the EU has adopted a horizontal directive that requires consistency with HACCP principles for a range of food items (Roberts and Greenwood 2003). Countries outside the EU have also adopted HACCP-based food-safety control systems.

CONCLUSIONS

The processing and regulation of foods are, at the commencement of the twenty-first century, poised to undergo significant changes that will have profound effects on the quality and safety of the food supply. Changes in food-safety regulation are the driving force and changes in the microbiological quality of foods will occur as a result of the changes in the food-safety approach, as an extension of prevention-based HACCP implementation. For example, in July 1996, the US government published a sweeping reform of food-safety rules for meat and poultry (FSIS 1996). The four major elements of the new rules were:

- Every plant must develop and implement a system of preventive controls, known as HACCP, designed to improve the safety of their products. The plant must demonstrate the effectiveness of the HACCP plan, which federal inspectors will continually verify.
- Every plant must regularly test carcasses for *E. coli* of fecal origin to verify the effectiveness of the plant's procedures for preventing and reducing fecal contamination, which is the major source of pathogenic bacteria.
- All slaughter plants and plants producing raw ground meat and poultry products must ensure that the *Salmonella* contamination rate is below the current national baseline incidence.
- Every plant must develop and implement written sanitation standard operating procedures as the foundation for its specific HACCP program.

The time-frame for implementation by large processing plants was 18–42 months depending on the size of the plant.

As systematic programs to reduce and eliminate contamination of products of animal origin are implemented, food-processing plants will critically review their processing operations as part of the hazard analysis component of HACCP. Inevitably steps in their processing will be identified that will affect the keeping quality (related to microbial spoilage) of their products and appropriate control procedures will be implemented to enhance the shelf-life and microbiological quality of the foods.

Despite decades of effort by the food industry and food regulatory agencies, it has not been possible to raise food animals free of pathogenic bacteria. In addition, many more problems of food-borne disease, caused by contaminated fresh fruits and vegetables, are being encountered, possibly as a result of increased worldwide production and movement of these commodities around the globe to meet consumer demands for year-round supplies. The growing conditions for fruits and vegetables vary widely in different parts of the world, thus it may be very difficult to avoid contamination with pathogenic bacteria. At the same time, populations in many developed countries are becoming more susceptible to infectious diseases because of immune deficiencies caused by age, chronic diseases, and immune-depressing infectious diseases. How can consumers be assured of a safe food supply? At least for the foreseeable future, an effective approach seems to be the decontamination of the final raw product. The use of γ-irradiation or electron accelerators for terminal decontamination of food of plant and animal origin may be among the best available options (Corry et al. 1995). Unfortunately, the use of γ-irradiation has been very limited due to public misconceptions about the radiation treatment of foods and the resulting reluctance of the food industry to utilize the process. There are other logistical problems relating to the use of radiation treatment for foods, including the need for transport of foods from processing plants to a central radiation treatment facility, safety problems associated with the use of radioactive materials, and problems associated with the disposal of radioactive wastes. Electron accelerators are more convenient as they do not use radioisotopes. However, their primary limitation is the inability to penetrate more than 1–2 cm below the surface of the food. The ideal decontamination method for uncooked foods still remains to be developed.

GENERAL COMMENTS

For the first 9 months of life, the human fetus lives in a sterile environment protected from microbes, except when pathogens such as cytomegalovirus, rubella virus, or *Toxoplasma* are able to infect the child transplacentally. This state of sterility comes to an abrupt end, however, at the time of birth when the newborn is confronted with the mother's vaginal microbes and environmental organisms. The infant's skin surface is initially colonized and then the oropharynx, gastrointestinal tract, and other mucosal surfaces rapidly become populated. Through the duration of the individual's life, the microbial population evolves, with many organisms, transient colonizers, and others becoming well-established, permanent residents. It is important to recognize that this is a normal phenomenon. Even those microbes with the well-recognized ability to cause serious disease are normally found in and on the human body. Indeed, one hallmark of pathogenesis is not the recovery of a specific organism, but rather the recovery of the organism in a normally sterile site and associated with a pathologic response (e.g. inflammatory cells). For example, *Escherichia coli* is a normal resident in the gastrointestinal tract. To find it there can be anticipated. However, *E. coli* should remain confined to the gastrointestinal tract. If it is found in the abdominal cavity or the patient's blood, this would be considered abnormal. Likewise, organisms such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Neisseria meningitidis*, and *Haemophilus influenzae* are all capable of causing lower respiratory tract infection. Recovery of these organisms in lower airway secretions would be consistent with their role in disease; however, isolation of the same organisms in a throat washing could be considered insignificant. Naturally, there are certain organisms whose recovery in humans is always associated with clinically significant disease (e.g. *Bacillus anthracis*, *Brucella* spp., *Francisella tularensis*, and *Salmonella typhi*, to name just a few). However, the majority of microbes responsible for human disease are commonly part of the normal microbiota that are able to invade normally sterile tissues and spaces. For that reason, it is important to know the normal habitats of the organisms associated with humans and to understand their capacity for producing disease.

It should also be appreciated that microbes serve a useful purpose in their human hosts. The normal microbiota maintain a protected environment that prevents colonization with potentially pathogenic organisms. For example, *Clostridium difficile* is able to produce gastrointestinal disease ranging from diarrhea to pseudomembranous colitis only when the normal intestinal flora has been reduced or eliminated by antibiotics. The production of proteolytic enzymes by microbes augments host factors in the digestion of foods. Likewise, the disruption of the normal microbial flora can interfere with this process. For example, when the bacteria in the small

intestine are replaced by colonic bacteria following small-bowel stasis (blind loop syndrome), bile salts that are secreted into the intestines are metabolized by *Bacteroides* spp., producing a resultant malabsorption syndrome. Intestinal bacteria can also synthesize vitamins (e.g. biotin, pantothenic acid, pyridoxine, riboflavin, vitamin K), many of which are required for the growth of other bacteria. For example, strains of *E. coli* can produce vitamin K, which is utilized as a required growth factor by *Porphyromonas melaninogenica*, which in turn produces penicillinases that protect other bacteria from penicillin. Thus, a complex relationship among the microbial species can be established for the mutual benefit of each organism and the host.

It is important to define certain terms. The interaction between microbes and humans can result in three general outcomes: disease, transient colonization, and prolonged colonization. Another term for colonization is infection, which does not imply disease but rather the association of the microbe with the human host for a period of time. Disease results when the interaction between microbe (e.g. bacterium, fungus, virus, or parasite) and human host results in a pathological process. This process can be due to microbial factors (e.g. hydrolytic enzymes, toxins) or the host's immune response to the presence of the organism. A few organisms have a high virulence potential and are always associated with disease, whereas most organisms are opportunistic pathogens and cause disease only when the host's immunity is suppressed or when the organisms are introduced into tissues in which they are able to express their virulence potential. The other two outcomes of microbe and host interaction result in colonization, either transiently or prolonged. It should be noted that transient and prolonged colonization implies a distinction based on the duration of the interaction. Although no specific time limit can be used to define colonization, it may be as short as hours to a few days (e.g. organisms passing through the gastrointestinal tract) or extend to weeks, months, or even years. The complex population of microbes that become established in a host are called a variety of names, including natural, indigenous, resident, and normal flora. In previous editions of this text, they were referred to as 'normal microbiota,' a term that has been retained here.

An individual is exposed to numerous organisms that colonize other human hosts and animals or are present in the air that is breathed and food and liquids that are consumed (refer to other chapters in this text that discuss the microbiology of air, soil, water, milk, and food products). Factors that determine whether exposure to a microbe results in transient passage through a human host or prolonged colonization are complex, involving environmental factors, host characteristics, and microbial properties. Nutrients and environmental conditions must favor the survival of microbes. For example, vegetative forms of *Bacillus* and *Clostridium* spp. cannot survive prolonged exposure to desiccation or heat. However, spores of these bacteria can exist in nature for months to years. Gram-positive bacteria have a thick peptidoglycan layer in their cell wall, which promotes osmotic stability and enables these organisms to exist on dry surfaces (e.g. household articles, hospital bed linens, skin surfaces). By contrast, gram-negative bacteria have a relatively thin peptidoglycan layer and a lipoprotein outer membrane. These structures reduce gram-negative bacteria to a more fragile state, restricting their survival to moist, protected areas (e.g. standing water, vegetation, sinks, and showers). Thus, exposure to gram-positive bacteria is frequently by person-to-person contact or exposure to contaminated fomites, whereas gram-negative bacteria are usually acquired following consumption of contaminated food or drink or exposure to a contaminated water source.

Various host factors determine the success of colonization with a microbe. Although the skin forms a barrier, preventing penetration of microbes into the deeper tissues, colonization of the surface is accomplished by organisms that can tolerate the dry surface and that are resistant to fatty acids produced by anaerobic bacteria and from the metabolism of sebum triglycerides. Some organisms are adapted to grow in skin areas with a high moisture content (e.g. axilla, skin folds, perianal area), whereas other organisms survive in hair follicles. The presence of lysozyme in tears and other secretions is highly toxic for many bacteria and restricts the organisms that can colonize these areas. Inhaled organisms can be rapidly trapped in the nasal passages, engulfed with secreted mucus, and either expelled or swallowed. Organisms ingested with food or drinks are frequently eliminated when exposed to the acidic environment of the gastric system or simply passed through the digestive tract. Other organisms fail to survive interaction with locally secreted antibodies, exposure to bacteriocins produced by the normal microbiota, or the localized environment (e.g. acidic pH of the vagina). The age of the host influences microbial colonization. The presence or absence of teeth, hormone secretions that are initiated at the time of puberty or altered in menopause, sexual activity, person-to-person interactions in day-care facilities, the military, or nursing homes, alteration of dietary habits, and many other age-related factors determine which organisms an individual is exposed to and which will become successfully established as a part of the normal microbiota.

The final factors that determine the success of an organism to colonize the human body are properties of the specific organism. For example, the terrain of the oropharynx is diverse, with opportunities for organisms to colonize saliva, the mucosal surface, the tongue, the gingiva above and below the tooth line, and teeth. Extremely oxygen-sensitive bacteria are able to proliferate in the gingival crevices where the *E*h is

appropriately low. Organisms such as *Streptococcus mutans* and *Streptococcus sanguis* adhere to the hard, smooth surface of teeth by producing extracellular polysaccharides (e.g. glucans, dextrans, fructans) from dietary carbohydrates. A pellicle consisting of proteins from saliva and crevicular fluids initially forms on the enamel surface, which forms the anchor for the streptococcal polysaccharides. Subsequent layering of proteins, bacterial polysaccharides, and mixed populations of bacteria leads to the formation of plaque on the tooth surface. Bacteria can also bind to cells lining the oropharynx, intestine, and vagina via specific receptors for the bacterial pili. This ability to adhere can prevent the mechanical elimination of organisms when saliva washes the oropharynx and food and drink pass through the intestines.

With the complex environmental, host, and microbial factors that shape the normal microbiota, it should be appreciated that this population of organisms is constantly changing in an individual. For example, performing tests to determine which microbes colonize an individual's oropharynx provides data for that individual at a discrete point in time. Surveys that estimate the prevalence of colonization with microbes are at best an approximation for the individuals sampled. The ability to apply microbial colonization data from the individual studied to another person is dependent on the similarities between the two individuals. The data collected become more useful if the number of individuals studied is increased and the host factors minimized (e.g. study individuals with a broad age range, include immunocompetent and immunosuppressed patients, etc.). Furthermore, the utility of the data is determined by the thoroughness of the microbiological procedures. Adequate types and volume of specimens must be collected and transported to the laboratory in a manner that preserves the viability of the microbial population; isolation, detection, and identification procedures that will permit recognition of all significant organisms must be used. Unfortunately, studies of the normal microbiota are limited by the numbers of individuals that can be studied using comprehensive microbiological techniques. In addition, refinements in microbiology procedures and changes in the taxonomic classification of microbes make it difficult to compare results of recent studies with those published in the older literature. Finally, molecular techniques have led to the recognition of many bacteria that cannot be isolated in culture. Despite these cautions, extensive literature exists that estimates the prevalence of organisms in different body sites. Table 1 is a summary of this literature for the four major body sites that are populated with the most common bacteria colonizing humans: respiratory tract, gastrointestinal tract, genitourinary tract, and the body surface. The table indicates whether the organisms are commonly present or not present in healthy individuals. The frequency with which these organisms are recovered is discussed in the following text. The source of this information is from the accompanying chapters in this edition, as well as the review articles and reference works that are listed at the end of this chapter (Balows et al. 1988, 1992; Boone and Castenholz 2001; Clarke and Bauchop 1977; Drasar and Hill 1974; Holt et al. 1994; Jousimies-Somer et al. 2002; Maibach and Hildick-Smith 1965; Mandell et al. 2000; Murray 1998; Noble and Sommerville 1974; Rosebury 1961; Skinner and Carr 1974). The taxonomic classification of the organisms listed herein is consistent with the *Manual of clinical microbiology* (Murray et al. 2003) and websites listing currently accepted bacterial nomenclature: www.bacterio.cict.fr (Society for Systemic and Veterinary Bacteriology) and www.dsmz.de/bactnom/bactname.htm.

NORMAL MICROBIOTA OF THE RESPIRATORY TRACT

The respiratory tract can be divided anatomically into the upper airways, which includes the anterior and posterior nares and the nasopharynx, the middle airways, comprised of the oropharynx and tonsils, and the lower airways, with the larynx, trachea, bronchi, and lungs. This classification serves as a useful foundation for examining the dynamics of airway colonization. The structural and physiological differences at each site provide an environment compatible for some organisms and hostile for others.

Nares and nasopharynx

Relatively small numbers of organisms are present in the nares, with *Staphylococcus*, including *S. aureus* and coagulase-negative species, *Corynebacterium*, *Peptostreptococcus*, and *Fusobacterium* species being the most numerous. The carriage rate of *S. aureus* in the anterior nares is higher in preadolescent children than in adults. The recovery of other organisms in the nares is common, but they are usually present transiently and in small numbers. The microbial population in the nasopharynx is more complex, with a predominance of streptococci and *Neisseria* species. The viridans streptococci can be readily recovered in the nasopharynx, with *Streptococcus salivarius* and *Streptococcus parasanguis* most commonly isolated, as well as *Streptococcus pneumoniae*. Many species of *Neisseria*, including *N. meningitidis*, have been recovered in nasopharyngeal cultures. Colonization with *N. meningitidis* varies from less than 10 percent to as great as 95 percent, with the highest incidence in young adults confined to institutions and in the military, where focal epidemics of meningococcal disease are observed. The most commonly isolated species of *Neisseria* are *Neisseria subflava*, *Neisseria sicca*, *Neisseria cinerea*, *Neisseria mucosa*, and *Neisseria*

Table 1 *Human microbiota*

GI, gastrointestinal tract; GU, genitourinary tract; skin, includes ears and eyes as well as skin.

lactamica. Multiple species coexist in more than half of all individuals. Related gram-negative coccobacilli that colonize the nasopharynx include *Moraxella catarrhalis*, now recognized as a common cause of respiratory tract infections (e.g. sinusitis, bronchitis), and *Kingella* spp. Unencapsulated strains, as well as occasional encapsulated strains, of *H. influenzae* are commonly found in the nasopharynx, as is *Cardiobacterium hominis*, an organism associated with infections of previously damaged heart valves.

Oropharynx and tonsils

The oropharynx is a complex mixture of ecosystems, each with a distinctive microbial population. Thus, predictable differences in organisms will be found in saliva, gingival crevices, surfaces of teeth, the tongue, and the mucosal lining. Gram-positive and gram-negative cocci predominate in the oropharynx. Overall, anaerobes outnumber aerobic bacteria 100 to 1. The most common anaerobic bacteria are *Peptostreptococcus*, related gram-positive cocci (i.e. *Micromonas*, *Peptoniphilus*), *Veillonella*, *Actinomyces*, and *Fusobacterium*; the most common aerobic bacteria are *Streptococcus* and *Neisseria*.

Relatively small numbers of staphylococci are present, although it has been estimated that as many as 20 percent of individuals are colonized with *S. aureus*. Streptococcal species are more numerous, particularly members of the viridans group. *S. salivarius* is present in high numbers in saliva (as the name implies) and on the surface of the tongue. Tooth surfaces are colonized with *S. sanguis* and *S. mutans*, whereas the oral mucosa is populated with *Streptococcus vestibularis* and *S. sanguis*. Other streptococci that colonize the oropharynx include *S. pneumoniae*, commonly present in children and adults with children, and β-hemolytic streptococci, including groups A, C, F, and G. Group A *Streptococcus* (*Streptococcus pyogenes*, the organism responsible for streptococcal pharyngitis) can transiently colonize healthy individuals or become a more permanent member of the oral microflora. Other gram-positive cocci that are present in the oropharynx include *Rothia mucilaginosa*, *Gemella* species, *Peptostreptococcus anaerobius*, *Micromonas micros*, and *Abiotrophia* species. Both *Rothia* and *Peptostreptococcus* are found in virtually all individuals.

As in the nasopharynx, gram-negative cocci and coccobacilli can colonize the oropharynx. *Veillonella* species are the most numerous gram-negative cocci found in the oropharynx, representing as much as 15 percent of the total bacterial population. *Veillonella atypica* and *Veillonella dispar* are present on the tongue, oral mucosa and in saliva. *Veillonella parvula* is present in subgingival spaces and in dental plaque, in higher numbers in dental caries. Other gram-negative cocci and coccobacilli include *Neisseria*, *Moraxella*, *Kingella*, *Cardiobacterium*, and *Eikenella*. *Eikenella corrodens* can establish residence in the oropharynx by adhering to buccal epithelial cells.

Gram-positive bacilli are also prominent members of the oropharyngeal flora. *Actinomyces* are present in large numbers, comprising 20 percent of the bacterial flora in saliva and on the tongue, 35 percent in gingival crevices, and 40 percent of the bacteria in dental plaque. The *Actinomyces* spp. present in the oropharynx are *Actinomyces israelii*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, *Actinomyces meyeri*, *Actinomyces georgiae*, and *Actinomyces gerencseriae*. *A. israelii* and *A. naeslundii* also colonize the surface of the tonsils. The ability of *Actinomyces* spp. to colonize the various surfaces is mediated by the presence of fimbriae that can adhere to mucosal cells and the production of extracellular polysaccharides that form a slime over tooth surfaces, entrapping organisms and preventing their removal by the flow of saliva and food through the oropharynx. Other genera of gram-positive bacilli present in the oropharynx include *Bifidobacterium*, *Corynebacterium*, *Eubacterium*, *Lactobacillus*, *Propionibacterium*, and *Rothia*. *Bifidobacterium dentium* is isolated in dental plaque and species of *Lactobacillus* are prominently associated with carious teeth, thriving in the acid environment produced by the streptococci responsible for the development of caries. *Eubacterium* spp. are isolated from subgingival crevices, dental plaques, and calculus.

The predominant gram-negative bacilli in the oropharynx are anaerobes, including *Fusobacterium*, *Bacteroides*, *Porphyromonas*, *Prevotella*, and *Selenomonas*. *Fusobacterium nucleatum* is the most common fusobacterium in the mouth, *Fusobacterium alocis* and *Fusobacterium sulci* are isolated in the gingival crevices, and the other species are present in smaller numbers throughout the mouth. Many of the anaerobic gram-negative bacilli in the mouth that were formerly classified as *Bacteroides* are now *Prevotella* and *Porphyromonas* spp. However, at least four species found in the mouth have been retained in the genus *Bacteroides*, while multiple species of *Prevotella* and two *Porphyromonas* species colonize the mouth. At least six species of *Selenomonas* are present in the oropharynx, primarily in gingival crevices.

Haemophilus spp. are present in almost all individuals although in small numbers (<5 percent of the microbial population). *H. parainfluenzae* is the most common *Haemophilus* species present in the mouth. *H. influenzae* is less commonly present, with most strains nonencapsulated. Other species are found on the tongue, palate, cheeks, and teeth, associated with dental plaque and periodontal disease. *Actinobacillus actinomycetemcomitans* is commonly isolated in the oropharynx and is an important cause of juvenile periodontitis. Another group of bacteria commonly found in the oropharynx, particularly in the gingival crevices, and associated with periodontal disease are *Treponema* species.

Members of the Enterobacteriaceae and nonfermentative gram-negative bacilli, such as *Pseudomonas* spp. and *Acinetobacter* are present in the oropharynx of healthy individuals, but usually only in small numbers or transiently. This changes in debilitated or hospitalized patients in whom these organisms can become the predominant bacteria in the oropharynx and are frequently responsible for lower respiratory tract disease.

Trachea, larynx, bronchi, and lungs

Colonization of the lower airways is generally transient, with relatively few organisms present at any one time. The only time long-term colonization occurs is when the ciliated epithelial cells are damaged through infection (e.g. with influenza virus) or disease (e.g. chronic obstructive pulmonary disease). This permits drainage of respiratory secretions into the bronchials and lower airways, with subsequent proliferation of the microbes.

NORMAL MICROBIOTA OF THE GASTROINTESTINAL TRACT

As with the respiratory tract, the gastrointestinal tract can be subdivided into distinct anatomical areas, each harboring its own indigenous microbiota. These would include the esophagus, stomach, jejunum and upper ileum, distal small intestine, and large intestine. It should be obvious that within each of these areas, the microbial flora on the mucosa, within crypts, and in the lumen can also be different. Unfortunately, the ability to sample each area without contamination from other sites in healthy individuals is limited. The most complete information has been obtained for the stomach and the large intestine. The microbial flora at other sites is estimated by studying the microbial composition of feces or the specimens collected at the time of intraabdominal surgery.

Esophagus

Insufficient information is available about the microbial flora of the esophagus. However, oropharyngeal bacteria can be isolated from this site, as can the organisms that colonize the stomach. Transient colonization occurs with these organisms in healthy individuals. In the diseased state, bacteria are uncommon causes of esophagitis and esophageal infections, with yeasts (e.g. *Candida*) and viruses (e.g. herpes simplex, cytomegalovirus) playing a more prominent role.

Stomach

The stomach is an inhospitable organ, containing hydrochloric acid and pepsinogen (a precursor of pepsin) secreted by parietal and chief cells, respectively, which line the gastric mucosa. For this reason, the normal microbial microbiota are sparse, primarily associated with the surface epithelium, and protected by secretions of mucus and bicarbonate. The organisms present in the stomach are acid-tolerant *Lactobacillus* spp., *Streptococcus* spp., and *Helicobacter pylori*. Whereas the first two organisms are not associated with gastric disease, *H. pylori* causes gastritis and gastric (peptic) and duodenal ulcers, and is associated with gastric malignancies. Other organisms may be isolated in the stomach, particularly a few hours after a meal, but are believed to represent transient passage through the stomach.

Jejunum and upper ileum

The number of microbes in the upper portion of the small intestine is low (generally fewer than 10^5 organisms per milliliter of fluid) and predominantly anaerobic, consisting primarily of *Lactobacillus*, *Streptococcus*, *Peptostreptococcus*, *Anaerococcus*, *Finegoldia*, *Peptoniphilus*, *Porphyromonas*, and *Prevotella*. If upper-tract obstruction and stasis occur (e.g. blind loop syndrome), then the microbial flora can shift to resemble colonic bacteria (e.g. *Bifidobacterium*, *Bacteroides*, *Clostridium*, *Escherichia*, *Enterococcus*) and lead to a malabsorption syndrome.

Distal small intestine

This is the transition area between the relatively sparse numbers of acid-tolerant bacteria that occupy the upper portion of the intestinal tract and the plethora of microbes that exist in the large intestine. Although it is unclear which organisms colonize this portion of the gastrointestinal tract permanently, it is known that the microbial population is large (approximately 10^8–10^9 organisms per gram of feces) and diverse, with a distinct predominance of strict anaerobes.

Large intestine

This is the most densely populated organ in the human body, with more than 10^8 aerobic bacteria and 10^{11} anaerobic bacteria per gram of feces. The most numerous bacteria in the large intestine are *Bifidobacterium* spp., *Bacteroides* spp., *Eubacterium* spp., *Enterococcus* spp., and *E. coli*. It has been estimated that feces consist of 10^{11} bacteroides per gram. Although *B. fragilis* is the most virulent species, *Bacteroides thetaiotaomicron* is more numerous in the colon. Other *Bacteroides* spp. in the colon include *Bacteroides capillosus*, *Bacteroides coagulans*, *Bacteroides putredinis*, and *Bacteroides ureolyticus*. *Eubacterium* spp. are the second most commonly isolated bacteria in the intestine, with more than 10^{10} organisms per gram of feces and 16 distinct species described. The most commonly isolated species are *Eubacterium aerofaciens*, *Eubacterium contortum*, *Eubacterium cylindoides*, *Eubacterium lentum*, and *Eubacterium rectale*. Ten species of *Bifidobacterium* have been isolated in feces, some species isolated preferentially from infants and others from adults. The most commonly isolated species are *B. bifidum*, *B. longum* and *B. adolescentis*. Many species of *Enterococcus* have been described, most of which are present in the human intestines. *Enterococcus faecalis*,

Enterococcus faecium, *Enterococcus casseliflavus*, and *Enterococcus gallinarum* are most frequently isolated. *E. coli* inhabits the intestine of virtually all humans, establishing intestinal colonization soon after an infant is born. Although it represents a relatively minor position quantitatively (approximately 1 percent of the total bacterial population), it is the most common facultative organism responsible for intra-abdominal infections.

A large number of other organisms have been demonstrated to colonize the large intestine. *Actinomyces* are frequently isolated in fecal specimens, even though intestinal colonization has not been clearly demonstrated. *Streptococcus* spp., including *Streptococcus bovis*, which is associated with intestinal malignancies, have been isolated from fecal specimens.

Gemella morbillorum is a member of the normal intestinal flora, as are a variety of gram-positive anaerobic cocci (e.g. *Anaerococcus prevotii*, *Finegoldia magnus*, *Peptoniphilus asaccharolyticus*). The spore-forming *Bacillus* spp. and *Clostridium* spp. are isolated in fecal specimens. Although this may represent simple transit through the gastrointestinal tract following ingestion with food or drink, most authors believe that *Clostridium* spp. are part of the permanent intestinal population. *V. parvula* can colonize the intestinal tract of humans, although it is generally present in small numbers. Like *E. coli*, other members of the Enterobacteriaceae can establish residence in the intestines. *Citrobacter* spp., *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., and various other genera can be consistently isolated in fecal specimens. *Haemophilus* spp. can be recovered in fecal specimens if selective media are used. Other organisms commonly isolated, but in small numbers, include species of *Fusobacterium*, *Porphyromonas*, and *Prevotella*. Uncultivable species of *Treponema* have been observed in fecal specimens.

NORMAL MICROBIOTA OF THE GENITOURINARY TRACT

The genitourinary tract is relatively sterile, with the exception of the female urethra and vagina. Microbes can migrate up the urethra into the bladder, but these are rapidly cleared in healthy individuals by the action of localized antibodies, microbicidal activity of the epithelial cells lining the bladder, and the flushing action of voided urine. The ureters, kidneys, prostate, and cervix are normally sterile. The female urethra is colonized with large numbers of lactobacilli, streptococcal species, and coagulase-negative staphylococci. Fecal organisms such as *Escherichia coli* and *Enterococcus* spp. can also colonize the female urethra but are generally transient and present in small numbers. When these latter organisms migrate up into the bladder, they are able to proliferate in urine and can establish a urinary tract infection.

The microbial flora in the vagina are more numerous and diverse. Lactobacilli are the predominant organisms because they are able to proliferate in the acidic environment. The most commonly isolated species include *Lactobacillus acidophilus*, *Lactobacillus fermentum*, *Lactobacillus casei*, and *Lactobacillus cellobiosus*. Other anaerobes commonly isolated in vaginal secretions are *Bifidobacterium*, anaerobic cocci, *Porphyromonas*, and *Prevotella*. Six species of *Bifidobacterium* have been recovered in the vagina; *B. bifidum* and *B. longum* are the most numerous. Likewise, eight species of anaerobic cocci (i.e. *Peptococcus niger*, *Peptoniphilus asaccharolyticus*, *Anaerococcus hydrogenalis*, *A. lactolyticus*, *A. prevotii*, *A. tetradius*, *Finegoldia magna*, and *Peptostreptococcus vaginalis*) reside in the vagina. *Porphyromonas asaccharolytica*, *Prevotella bivia*, and *Prevotella disiens* are also important residents of the vagina. *Actinomyces* spp. are believed to be present in the vagina because they are associated with vaginal infections. However, demonstration of their presence is controversial. *A. israelii* is most commonly associated with genital actinomycotic infections. *Propionibacterium*, particularly *Propionibacterium propionicus*, is also present in the vagina. Finally, *Mobiluncus* spp. are relatively uncommon in healthy women but a significant cause of bacterial vaginosis. Thus, it is likely that this anaerobe is present in the vaginal microbial flora in small numbers.

Common aerobic bacteria present in the vagina include *Staphylococcus* (primarily coagulase-negative species), *Streptococcus*, and *Corynebacterium* spp. The viridans group and β-hemolytic strains (e.g. groups B, C, and G) of streptococci are present in the vagina. *Gardnerella vaginalis* can also colonize the human genital and urinary tract, although it is only present in high numbers in women with vaginosis and their male partners. *Neisseria* spp., including *N. meningitidis*, are recovered in vaginal secretions, as are species of *Haemophilus* (including *H. influenzae* and *H. parainfluenzae*). Although these organisms can be recovered from a large proportion of individuals, they are generally part of the minor bacterial population. Members of the Enterobacteriaceae, particularly *E. coli*, can be found in the vaginal flora, although generally in small numbers. *Weeksella virosa* is almost exclusively isolated in genital specimens, particularly from sexually active women. Three species of nonpathogenic *Treponema* (*Treponema phagedenis*, *Treponema refringens*, and *Treponema minutum*) are isolated in vaginal specimens.

Six species of *Mycoplasma* (*Mycoplasma hominis*, *Mycoplasma genitalium*, *Mycoplasma fermentans*, *Mycoplasma primatum*, *Mycoplasma spermatophilum*, and *Mycoplasma penetrans*) primarily colonize the genitourinary tract. In addition, the related organism *U. urealyticum* is a common inhabitant of this site. The role of these organisms in disease is controversial, but clearly

M. hominis and *U. urealyticum* have pathogenic potential.

NORMAL MICROBIOTA OF THE BODY SURFACE

The surface of the skin is relatively inhospitable in comparison with other body sites. It is exposed to extremes in temperature and moisture and to chemical disinfectants such as soaps and shampoos. It is not surprising, therefore, that the microbial population is less numerous and complex than at other body sites. Despite this observation, many organisms, particularly gram-positive bacteria, are able to establish permanent residence on the skin surface. Transient colonization with a diverse array of environmental and endogenous microbes can also occur.

As with other areas of the body, the skin should not be considered a homogeneous surface, but rather a landscape of mountains and valleys, each with a specific environment and microbial population. Thus, there are relatively dry, hairless areas such as palms and soles, areas with a proliferation of apocrine glands such as the axillae, inguinal, and perineal areas, and areas rich with sebaceous glands such as the forehead and nasolabial folds. Each area is associated with distinct microbes. Most microorganisms proliferate in a moist environment, hence higher densities of microbes are present in areas rich with sweat glands or on occluded surfaces. The skin proximal to the oral cavity (face), gastrointestinal tract (perirectal area), or genitourinary tract (groin) has a more complex microbial flora than at other surface sites, although most of these organisms result from surface contamination and only transiently colonize the skin surface.

Anaerobic bacteria are ten- to 100-fold more numerous on the skin surface compared with aerobic bacteria; gram-positive bacteria predominate over gram-negative bacteria. The bacteria most commonly recovered on the skin surface are members of the genera *Staphylococcus*, *Micrococcus*, *Corynebacterium*, *Peptococcus*, *Peptoniphilus*, *Finegoldia*, *Peptostreptococcus*, and *Propionibacterium*. *Staphylococcus epidermidis* is the most frequently isolated bacterium, present on surfaces where the moisture is highest. Other coagulase-negative staphylococci that are found on the skin include *Staphylococcus hominis*, *Staphylococcus haemolyticus*, *Staphylococcus warneri*, *Staphylococcus capitis* (particularly on the forehead and face after puberty), *Staphylococcus saprophyticus*, *Staphylococcus caprae*, *Staphylococcus saccharolyticus*, *Staphylococcus pasteuri*, *Staphylococcus lugdunensis*, *Staphylococcus simulans*, and *Staphylococcus xylosus*. *Staphylococcus auricularis* is the most common species found colonizing the exterior auditory canal. The coagulase-positive *S. aureus* can colonize the skin adjacent to the nares and in moist folds and, less frequently, at other sites.

Micrococcus luteus is the most common *Micrococcus* sp. present on the skin, found in virtually all adults and representing as much as 20 percent of the bacterial population on the head, legs, and arms. However, relatively few micrococci are present in areas with a high moisture content and other competitive bacteria (e.g. axillae, nares). Additional gram-positive cocci (formerly classified as *Micrococcus*) that colonize the skin surface include *Dermacoccus nishinomiyaensis*, *Kocuria kristinae*, *Kocuria rosea*, *Kocuria varians*, and *Kytococcus sedentarius*.

Aerococcus viridans, *S. pyogenes*, and various anaerobic *Peptostreptococcus* spp. can also establish residence on the skin surface. *Aerococcus* is an airborne bacterium, so the incidence of true colonization versus contamination and transient colonization is unknown. *S. pyogenes* differ from other streptococci in their tolerance to the dry surfaces of the skin and to the bactericidal fatty acids from sebum and also produced by the anaerobic cocci and bacilli. Thus, they are particularly well suited for dry skin surfaces. Anaerobic cocci survive in the anaerobic niches of hair follicles and skin glands.

Many species of *Corynebacterium* spp. are present on the skin surface, including *Corynebacterium striatum*, *Corynebacterium minutissimum*, *Corynebacterium pseudodiphtheriticum*, *Corynebacterium xerosis*, *Corynebacterium urealyticus* (especially in the groin area), and *Corynebacterium jeikeium* (on moist surfaces rich in apocrine glands in hospitalized patients). The anaerobic counterpart to these aerobic gram-positive bacilli are the *Propionibacterium*. *Propionibacterium acnes* is found in high concentrations in areas rich in sebaceous glands, as is *Propionibacterium granulosum*. *P. acnes* is the predominant species, found in high numbers on virtually all individuals, whereas *P. granulosum* is recovered in small numbers and on fewer than 20 percent of individuals sampled.

Propionibacterium avidum, by contrast, requires an area high in moisture for survival and is most commonly found in axilla and perineum. Other resident gram-positive bacilli include *Dermabacter hominis*, *Brevibacterium epidermidis*, *Brevibacterium casei*, and poorly defined *Brevibacterium* spp. *Turicella otitidis* colonizes the external ear. Some species of *Bacillus* and *Clostridium*, particularly *Clostridium perfringens*, can colonize the skin surface due to their ability to form spores and withstand desiccation and detergents. However, they are generally present in small numbers and only transiently.

Gram-negative bacteria are generally not recovered from the surface of the skin, except during transient colonization. The outer portion of the cell wall of gram-negative bacilli consists of a lipid membrane that is unable to survive exposure to detergents or the dry surfaces of the skin. However, *Acinetobacter* spp. have adapted to survive in moist areas such as toe webs, the groin, and axillae. *Burkholderia* species can also colonize the skin surface but generally is found only transiently.

NORMAL MICROBIOTA OF BLOOD, CEREBROSPINAL FLUID, AND OTHER BODY FLUIDS

The human body is bathed in a variety of fluids, including blood, cerebrospinal, synovial, pleural, pericardial, peritoneal, and other exudates and transudates. All of these fluids are normally sterile or only transiently infected. Whereas microbes from the mouth or gastrointestinal tract can invade the bloodstream in healthy individuals (e.g. during tooth brushing or a bowel movement), these organisms are rapidly removed and generally of little or no significance. Thus, the isolation of an organism from a body fluid should be considered significant unless the specimen is contaminated during the process of collection.

NORMAL MICROBIOTA OF BODY TISSUES

As with body fluids, organ tissues are generally sterile unless they are infected following the systemic spread of an organism in the bloodstream. Some organisms (e.g. *Mycobacterium tuberculosis*) may be disseminated to tissues such as the lungs, liver, or kidneys at the time of initial infection and remain dormant for many years. In this situation it is possible that the organism could be recovered from tissue samples, but even that would be unlikely unless the disease process was active.

CONCLUDING COMMENTS

From the moment of birth until the terminal breath, the human body serves as a home for qualitatively and quantitatively numerous microbes. They cover the skin and mucosal surfaces of the body, occasionally invade into sterile tissues and fluids to produce disease, but more typically coexist with each other and their human host. These microbiota function as a microbial barrier to more virulent microorganisms, supplement the human host's mechanical and enzymatic digestion of food, provide vitamins and other required growth factors for their host, or simply exist as a commensal inhabitant on their host. The complexity of the microbiota is shaped over time by environmental, host, and microbial factors, but it is remarkably predictable for a general population. Certainly the dominant microbial species at each of the major body sites (e.g. respiratory tract, gastrointestinal tract, genitourinary tract, and body surface) are now well known. Variations from the expected population can predictably lead to disease (e.g. replacement of the microbial population of the small intestine with bacteria from the large intestine, leading to a malabsorption syndrome). Likewise, spread of bacteria from their normal habitat into sterile tissues and fluids can initiate well-characterized disease (e.g. colonic perforation leads to a polymicrobic peritonitis and intraabdominal abscess formation by *B. fragilis*). Thus, knowledge of the human microbiota forms a fundamental building block for our knowledge of the normal physiological processes in the human body and our understanding of infectious diseases.

Epidemiology of infectious diseases

STEPHEN R. PALMER AND MEIRION R. EVANS

Concepts in the epidemiology of infectious disease	1	The investigation of outbreaks	18
Epidemiological methods	3	Mathematical models of infectious disease	22
Epidemiological surveillance	9	References	24

Epidemiology is the study of the patterns of occurrence and causes of disease in populations. It does not stand alone, but is complementary to microbiology and environmental risk assessment methods of investigation. For general accounts of epidemiology see Hennekens and Buring (1987), Beaglehole et al. (1993), Detels et al. (2002), and Rothman (2002). The occurrence of an episode of microbial disease is a result of the interaction of the agent, host, and environmental factors that leads to the exposure of the host to sufficient numbers of the agent in the appropriate transmission mode. Successful investigation and control require that not only the microbiological, but also behavioral, genetic, environmental, and social factors which influence the occurrence and presentation of the disease be taken into account. Close collaboration between epidemiologists, microbiologists, and other public health workers is therefore essential. Accurate laboratory diagnosis is usually a major factor in successful control, though epidemiological methods alone may be sufficient to indicate appropriate interim control measures. For example, the modes of transmission and the risk behavior leading to the acquired immune deficiency syndrome (AIDS) were identified by epidemiological methods 2 years before the causative agent was discovered. Advice to the public about reducing the risk of infection did not need to be revised substantially when the human immunodeficiency virus (HIV) was identified. However, the discovery of HIV was a major advance and allowed the development of diagnostic tools that are now used to study epidemiological characteristics of the infection, e.g. incubation period, progression rate to AIDS, spectrum of clinical disease, period of infectivity. Increasingly, the epidemiological method is seen by microbiologists as a necessary tool in setting priorities for the use of scarce resources. Applications of epidemiology in microbiological disease include population surveillance to monitor trends in disease and infections and to detect case clusters, the investigation of sources and modes of transmission of microorganisms, applying public health measures to control outbreaks of disease, and devising and evaluating preventive and control programs.

CONCEPTS IN THE EPIDEMIOLOGY OF INFECTIOUS DISEASE

Reservoir of infection

This is where the infectious agent normally lives and where it may multiply or survive; it may be human (e.g. in chickenpox), animal (e.g. in brucellosis) or the inanimate environment (e.g. in tetanus).

Source of infection

Infection may be derived from the patient's own microflora (endogenous), or from another human being, or an animal (zoonosis) or an environmental source (exogenous). The source of an exogenous infection may sometimes be different from its reservoir. For example,

in an outbreak of cryptosporidiosis in Maine, the reservoir of infection was a herd of cattle on a farm that supplied apples for making apple cider. The apple cider then became the source of infection for human subjects. *Cryptosporidium* oocysts were detected in the apple cider, on the cider press, and in a stool specimen of a calf on the farm which supplied the apples (Millard et al. 1994). When the source of infection is inanimate, e.g. food, water, or fomites, it is termed the vehicle of infection.

Mode of transmission

The mechanism by which an infectious agent passes from the reservoir or source of infection to the person can be classified as follows.

FOOD-, DRINK-, OR WATER-BORNE INFECTION

Examples of this type of infection are typhoid and cholera. The term 'food poisoning' has in the past sometimes been restricted to incidents of acute disease in which the agent has multiplied in the food vehicle before ingestion (e.g. food-borne salmonellosis), or where it may have formed toxins (e.g. botulism).

DIRECT OR INDIRECT CONTACT

This includes spread from cases or carriers, animals, or the environment to other persons who are 'contacts'. Within this category possible routes include: feces-to-hand-to-mouth spread (e.g. shigellosis); sexual transmission (e.g. gonorrhea); skin or mucous membrane contact (e.g. wound infection, cutaneous anthrax).

PERCUTANEOUS INFECTION

This includes: insect-borne transmission via the bite of an infected insect either directly from saliva (e.g. malaria); or indirectly from insect feces contaminating the bite wound (e.g. typhus); transfusion of contaminated blood and inoculation of blood or blood products from needle stick injuries (e.g. hepatitis B); direct transmission through intact skin (e.g. schistosomiasis), or broken skin (e.g. leptospirosis).

AIR-BORNE INFECTION

Infectious organisms may be inhaled as: droplets (e.g. streptococcal pharyngitis); droplet nuclei (e.g. tuberculosis); aerosols (e.g. Legionnaires' disease); dust (e.g. ornithosis); or spores (e.g. anthrax).

TRANSPLACENTAL INFECTION

Examples include listeriosis, rubella, cytomegalovirus (CMV), and toxoplasmosis.

Occurrence

An infection that is continuously in a population is said to be endemic, whereas an increase in incidence above the endemic level is described as an epidemic, or pandemic when the epidemic is worldwide. Cases may be sporadic, that is, not known to be related to other cases or infections, or clustered in outbreaks which may be defined as two or more related cases or infections, suggesting the possibility of a common source or transmission between cases. Three commonly used measures of occurrence of disease or infection are the incidence rate, the rate of occurrence of new cases in a defined population (e.g. 10 cases per 100 000 persons per year); cumulative incidence or risk, which is the proportion of people who become diseased during a specific period; and prevalence, the proportion of a defined population with the disease at a point in time (point prevalence) or during a defined period of time (period prevalence). The prevalence of a disease depends upon its incidence and duration. In chronic diseases, prevalence may be high although incidence is low, but in short-duration infectious diseases prevalence approximates to incidence.

The attack rate during an outbreak is a type of cumulative incidence, the proportion of the population at risk at the beginning of a time period who became ill during the period. The secondary attack rate is the attack rate in the contacts of primary cases due to person-to-person spread.

Incubation period

This is the time from infection to the onset of symptoms (Richardson et al. 2001). For each organism there is a characteristic range within which infecting dose and portal of entry, as well as host factors such as age (Glynn and Palmer 1992) and immunosuppression, give rise to individual variability.

Host response

This depends upon the dose of the infecting agent and the susceptibility of the host, perhaps influenced by genotype, age, sex, other concurrent disease, immunity, and 'risk factors' such as smoking for Legionnaires' disease. In an outbreak of infection there is often a spectrum of clinical response ranging from no symptoms to fulminant disease and death.

Communicability

The infectious agent may be passed to others over a variable time, the period of communicability (Richardson et al. 2001); in some infections even from symptomless temporary or chronic carriers (e.g. *Salmonella* Typhi).

EPIDEMIOLOGICAL METHODS

Collection of observations

Investigation of the occurrence and distribution of disease requires accurate definition of the disease and its possible determinants and the measurement of their frequency in the population. A clear case definition is essential in epidemiological studies. If serological or cultural confirmation of the diagnosis is not possible, because a specific laboratory test is lacking or appropriate samples were not collected, the case definition will depend upon the clinical features as, for example, with AIDS before the discovery of HIV. During the investigation of an outbreak, laboratory confirmation of the diagnosis may be possible only in a few cases; a clinical definition will then need to be used in further studies. The specificity of the diagnosis in some patients may be doubtful; in these circumstances it is helpful to classify cases as 'definite', 'probable', or 'possible'. When case definitions are based on the presence of symptoms these must be precisely defined, e.g. 'by diarrhea we mean at least $\geqslant$3 loose or watery stools in a 24 h period', so that all respondents understand the questions in the same way and the comparability of different studies can be assessed.

Routine sources of data on infectious diseases are described in a later section. In detailed epidemiological enquiries, however, other sources must be used: medical records, interviews with patients, and questionnaires.

Medical records

Clinical records may contain data on symptoms, investigations performed and their results, and personal details of patients, but for epidemiological purposes clinical records are seldom sufficient. The data recorded are likely to be accurate but incomplete, since they are not normally collected in a standard way from each patient. Scrutiny of these records may be useful in confirming the reported diagnosis and assessing whether the patient meets the case definition, and laboratory records usually provide an invaluable source of microbiological data and data on age, sex, and the geographical distribution of cases. However, to obtain detailed, accurate clinical information, interviews with patients are usually required. For example, in a survey of hydatid disease, a review of clinical records yielded data on the patients' age, sex, and home address, and on the results of clinical investigations and pathological tests. However, data on past history of residence, occupation, and exposure to dogs were seldom recorded; this could be obtained only by questioning the patients (Palmer and Biffin 1987).

Epidemiological interviews and questionnaires

To ensure accurate and comparable records of all persons included in the enquiry and to facilitate analysis, the data should be collected on a carefully designed standard form or questionnaire. Whenever possible, the questionnaire should be tested on a few cases and changes made as necessary before use in the main study. Administration of the questionnaire will often be by direct face-to-face interview by a single investigator or group of investigators trained to administer the questionnaire. Interview by telephone may be useful in obtaining data quickly. When numbers are large and the enquiry is straightforward, a self-administered postal questionnaire is cheaper and quicker to administer, but the response rate and accuracy of the data may be less than those obtained by interview.

When designing questionnaires it is important to take into account the limitations of people's recall of events. For example, in one study, food consumption recalled by people 2–3 days after a luncheon was compared with that observed at the time and recorded on tape (Decker et al. 1986). Only four of 32 patients made no errors in reporting. The sensitivity of the food-history questionnaire was 87.6 percent and its specificity 96.1 percent. Thirteen percent of the respondents reported eating one or both of two food items that were on the questionnaire but not served at the luncheon. Such errors in recall can be reduced by providing background details of events, by design of good questionnaires, and by making use of other sources to check data, such as diaries, menus, discussion with relatives, etc. Random errors in recall are unlikely to give rise to false associations between illness and, for example, an item of food, but they will reduce the power of the study to identify the true vehicle of infection. For some types of data, such as history of immunization, recall by patients or parents is of very limited value; studies of vaccine efficacy usually require validation of vaccine history from medical records.

Descriptive analysis

Variables measured may be:

- fixed or discrete (e.g. sex, occupation, nationality) or
- continuous (e.g. age, white blood cell count).

Analysis of the distribution will usually be by calculation of proportions of people who fall within certain categories or rates of occurrence of disease within subgroups of the population. Analysis of continuous variables is more complex because values obtained from a population will form a continuous distribution, usually approximating to a normal or skewed normal distribution (Figure 1). This distribution may be summarized

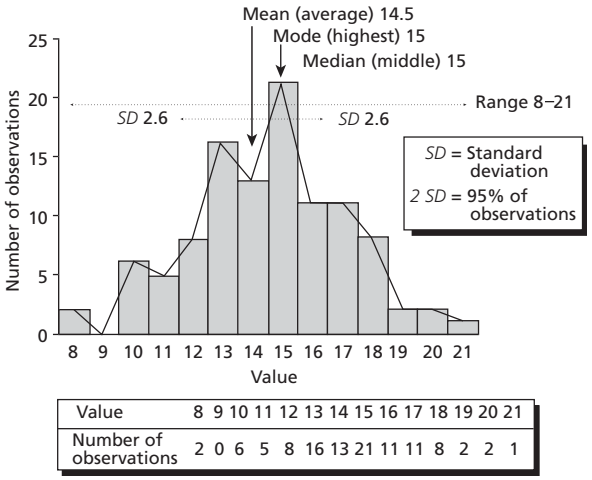

Figure 1 *Frequency distribution and measures of continuous variable*

by the mean, median, mode, and the standard deviation; these measures are commonly used to compare continuous variables in different populations.

The data should first be analyzed within the three classical epidemiological parameters of time, place, and person, taking into account interactions of these variables.

TIME

The epidemic curve is the most useful and immediate means of assessing the type of outbreak (Figure 2). In point-source outbreaks in which all cases are exposed at a given time, onset of symptoms of all primary cases will cluster within the range of the incubation period. For example, in the winter term of 1982, two campylobacter outbreaks were reported in boarding schools in the south of England. In the first of these (Figure 2a), 102 of 780 boys were admitted to the sanatorium with gastrointestinal illness, 46 of them on 1 day; this explosive outbreak was probably due to post-pasteurization contamination of the milk supply on one particular day. The other outbreak occurred in a school supplied with unpasteurized milk and was due to a continuing or recurring source of contamination. In this case the epidemic curve extended over several incubation periods (Figure 2b); 35 of 370 boys were admitted to the sanatorium over the first weeks of the term. In some outbreaks, a point-source of infection may be followed by person-to-person spread as in an outbreak of *Salmonella* Typhimurium, phage-type 10, infection affecting 66 students and one member of staff in a university hall of residence in Bristol in March 1980 (Palmer et al. 1981). The main wave of the outbreak was due to the

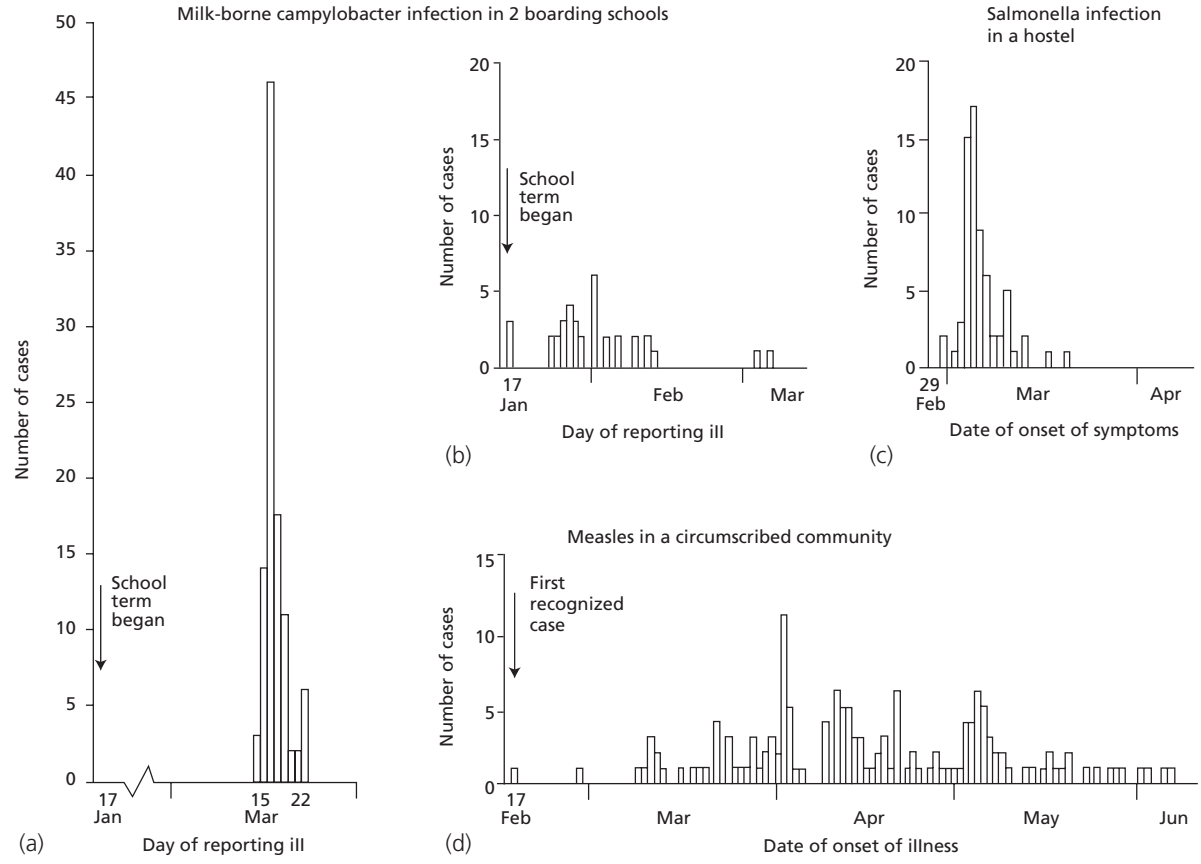

Figure 2 *The epidemic curve*

consumption of contaminated meat pie, but subsequent cases were due to person-to-person spread, prolonging the decline in the epidemic curve (Figure 2c). In outbreaks propagated from person to person the occurrence of cases will be spread over several incubation periods with peaks at intervals of the incubation period. For example, an outbreak of measles affecting 151 persons in a circumscribed rural community in Oxfordshire between February and June 1981 (Figure 2d) showed a smooth epidemic curve but with distinct peaks at 1, 2, 3, and 4 incubation-period intervals after the case (Knightley and Mayon-White 1982). In larger community outbreaks of diseases spread from person to person, the epidemic curve is usually smoother and the peaks at the generation time of the new cases less obvious.

The onset of disease and the epidemic curve should be studied in relation to other events in the environment of the patients; this may draw attention to possible sources of the infection. For example, investigation of a hospital outbreak of Legionnaires' disease in 1983 revealed that a few weeks earlier the domestic hot-water temperatures in the building had been reduced from approximately 55°C at outlets to 45°C, a temperature at which legionellae flourish. Subsequent investigations confirmed that the domestic water supply in the hospital was the source of infection (Palmer et al. 1986).

PLACE

The geographical distribution of disease may provide evidence of its source or method of spread. For example, the crucial factor in the recognition of Lyme disease and the role of tick bites in transmission of *Borrelia burgdorferi* was geographical clustering of presumed childhood rheumatoid arthritis in Old Lyme, Connecticut (Steere et al. 1978). Investigation revealed that the incidence of illness was higher in communities on the east than on the west side of the Connecticut River, and field studies showed that *Ixodes* ticks were particularly abundant in the former area. Case clustering in a particular place of work or neighborhood may indicate the existence of a point-source of infection or of person-to-person spread. In outbreaks of hospital-acquired infection, movement of patients between wards may hide clusters. It is therefore necessary to identify and plot the location of the patients at the time of likely exposure.

PERSON

This includes analysis by age, sex, occupation, and any other relevant characters which preliminary enquiries indicate may be relevant (e.g. food histories, history of travel, leisure activities, and medical or nursing care). For example, food-borne outbreaks of infection due to milk, ice cream, and confectionery characteristically affect children rather than adults. A sudden increase in isolations of *Salmonella* Ealing mainly affecting infants led to the recognition and early control of a nationwide outbreak of salmonellosis due to infant-formula dried milk (Rowe et al. 1987). In contrast, in an outbreak of *Salmonella* Oranienburg infection in Norway in 1981 and 1982, 83 percent of 121 cases were aged 25 years or more, suggesting a food vehicle restricted to adults. This proved to be home-cured meats, the organism originating from contaminated black pepper used as one of the ingredients (Gustavsen and Breen 1984). In another outbreak, of *Salmonella* Cubana infection in hospital patients, the predominance of patients with gastrointestinal dysfunction led to identification of carmine dye, used in investigations, as the vehicle of infection (Lang et al. 1967).

Epidemiological surveys and analytical studies

Descriptive analysis may suggest hypotheses about the source or mode of transmission of an infection, but is not always a sufficient base for introducing control measures. Analytical epidemiology refers to the use of epidemiological techniques to answer specific questions or to test specific hypotheses. The epidemiological approach is complementary to the microbiological. For example, when microbiological investigations reveal legionellae in a cooling tower this does not in itself identify the source of infection because legionellae commonly colonize water systems without causing disease. Epidemiological evidence is necessary to demonstrate an association between exposure to contaminated water and disease.

EXPERIMENTAL AND INTERVENTION STUDIES

Studies of the efficacy of treatments and vaccines are usually undertaken by randomized controlled trials. Random allocation of people to treatment and nontreatment groups is used to overcome bias that can arise if treated and untreated groups differ in underlying factors. For example, if the groups differed in susceptibility to disease, this might produce a favorable result wrongly attributed to the treatment. Treated and untreated groups are then followed to determine the outcome, and incidence rates are compared. With the exception of vaccine trials, most measures of infectious-disease control have not been subject to randomized controlled trials (US Preventive Services Task Force 1996).

Figure 3 shows an epidemiological study design for an experimental study.

PREVALENCE AND INCIDENCE STUDIES

In prevalence or cross-sectional studies (Figure 4) the aim is to measure the proportion of a population with disease or other variable at a point in time. Prevalence studies are often used in descriptive epidemiology, for

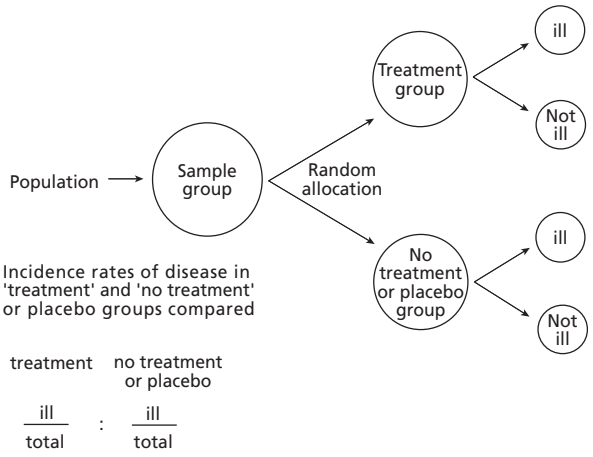

Figure 3 *Epidemiological study design – experimental study*

example, in the surveillance of HIV infection in which the proportions of different risk groups who are HIV-antibody positive are calculated at different times to monitor the spread of infection in the population. Crucial to the success of such studies is the representativeness of the sample of the population studied. For example, studies of AIDS and HIV infection are hampered by an inability to identify the population of homosexuals and drug abusers from which to select a representative sample. Patients attending clinics for sexually transmitted infections (STI) probably represent the extreme end of the spectrum of sexual activity and are likely to have the highest prevalence of HIV infection. On the other hand, high risk patients may attend private medical facilities, so that STI clinic populations cannot be considered necessarily representative even of highly sexually active homosexuals, although they may provide a suitable population for monitoring trends in infection.

The methodology of prevalence studies requires the definition of a population and the study sample. The list

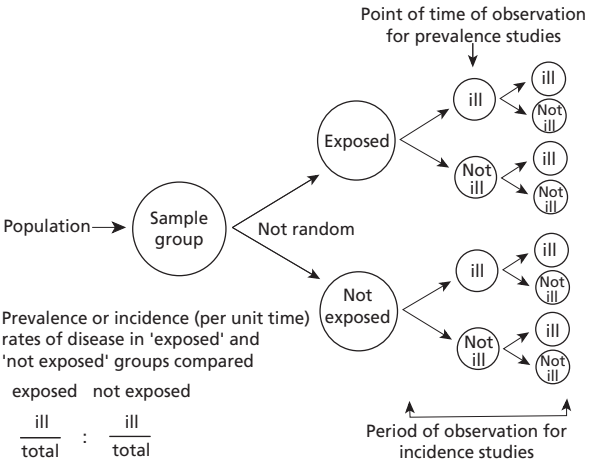

Figure 4 *Epidemiological study design – prevalence and incidence studies*

of names of the population (e.g. electoral register, school register, general practice age-and-sex register) is referred to as the 'sampling frame'; if a sample is to be taken this should be selected either by random, systematic, stratified or cluster sampling (Abramson 1999), so that findings are representative of the practice population. Information on the presence of disease or symptoms is collected by questionnaire or pro-forma, together with other data on personal characteristics or potential risk factors. The proportions of persons with various characteristics or exposures are then compared to identify high risk groups or exposures associated with high prevalence.

Incidence, longitudinal, or follow-up studies measure the rate of occurrence of disease. For these purposes, observations on the population must be made at more than one point in time. Incidence studies may be used descriptively, for example, in following the age incidence of measles to monitor the impact of measles vaccination in a community, in describing the natural history and fatality rates from HIV infection by following cohorts of infected people over several years, or in monitoring crossinfection rates in hospitals. However, they are often also used to test specific hypotheses.

Analytical cohort studies

The analytical cohort study is an application of the incidence study; it attempts to investigate causes of disease by using a natural experiment in which a proportion of a population is exposed and a proportion unexposed. It differs from the true experiment in that exposure is not controlled and may not be random; caution is therefore needed when interpreting the data. If the at-risk population is large, a random sample can be investigated and the results extrapolated to the total population.

Cohort studies may be prospective, when the disease occurs after the study has begun and the characteristics of the population have been identified. For example, in a study to identify risk factors for HIV infection, a serological survey of homosexual men was carried out and seronegative men were enrolled in the study. Baseline data on sexual activity were recorded, and 6 months later the sera of the same men were again tested and seroconversion rates were calculated for groups with a particular sexual behavior. Seroconversion rates were significantly higher in men practicing receptive anal intercourse (Kingsley et al. 1987) than in those who practiced other forms of sexual activity. In a study in the USA of the influence of socio-economic factors on the incidence and outcome of cytomegalovirus infection in pregnancy, two cohorts of women were selected by enrolling those attending a private clinic and those attending a state health department clinic. Seroconversion rates were significantly higher in the lower socio-economic group (Stagno et al. 1986).

Retrospective or historical cohort studies are possible when the population has been defined and identified previously for other purposes. In investigations of food-poisoning outbreaks that have taken place in an institution or after attendance at receptions it is usually possible to identify retrospectively all those exposed and to relate the attack rates to food consumed (food-specific attack rates).

Several possible types of bias may lead to misinterpretation of results of analytical studies and should be considered at the design stage. One potential problem is that of misclassification of cases and non-cases or misclassification of exposure. For example, in the outbreak already described, of *Salmonella* Typhimurium in 1981 in a university hostel, it was not possible to detect the vehicle of infection by comparing food-specific attack rates if a case definition based upon the presence of gastrointestinal symptoms was used. Feces samples were obtained from the whole cohort and only when symptomless excreters had been excluded from the well group did a significant difference in food-specific attack rates emerge (Palmer et al. 1991). To help overcome this problem it is usual to ask all the individuals in the cohort about symptoms over the appropriate time period, so that those who may have been unrecognized cases can be excluded from the analysis or reclassified as cases. The feasibility of serotesting, swabbing, or otherwise testing non-cases to exclude symptomless infected persons should always be considered. To avoid misclassification of exposure, it is desirable to verify exposures by obtaining records from independent sources (such as medical records, employment records) on all or a sample of the individuals in the study. Even quite small errors of classification can lead to misinterpretation of results as in a cryptosporidiosis outbreak in Nevada in 1994 that may have been wrongly attributed to waterborne transmission (Craun and Frost 2002).

Another important possible bias may arise from 'loss to follow-up'. The loss of cases or non-cases from the study because of refusal to be interviewed or failure to trace patients can seriously bias results since exposures in nonresponders may differ from those of responders. A poor response rate may invalidate the results of a study.

CASE-CONTROL STUDIES

The essential difference between a case-control study (Figure 5) and a cohort study is that the former begins with the identification of people with and without the infection and then attempts retrospectively to identify factors associated with disease. In cohort studies, on the other hand, groups of people are identified other than by the presence of disease, and then information on disease occurrence in this group is sought. When the population affected cannot be accurately determined or cases are few, case-control studies are appropriate. Their use should be confined to the testing of specific hypotheses. For example, in the outbreak of *Salmonella* Ealing infection in infants, the hypothesis that the vehicle of infection was infant-formula dried milk was tested by a case-control study that showed a strong association between illness and consumption of one particular brand. Subsequently, *Salmonella* Ealing was cultured from the milk powder and from the factory where it was produced (Rowe et al. 1987). Case-control studies are relatively quick and cheap to perform, but their design and analysis can be complex and special attention must be paid to potential sources of bias.

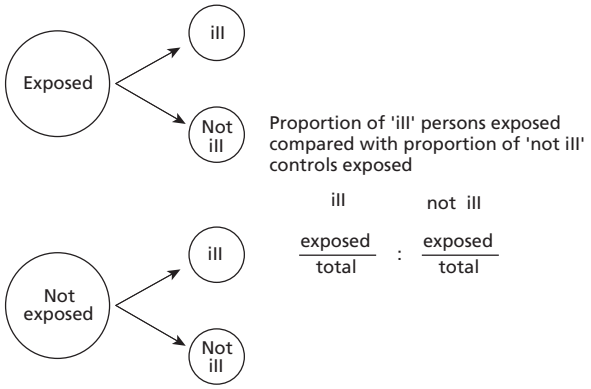

Figure 5 *Epidemiological study design – case-control study*

Cases and controls should be representative of the infected and uninfected population, respectively, from which they came and should have had equal opportunity for exposure to the suspected source. Possible bias in the detection of cases may occur if, for example, only patients admitted to hospital are studied; those who have died of fulminant disease or have only mild illnesses may as a result be excluded. Variables significantly associated with disease in a biased sample may merely reflect the factors that caused the bias, for example, admission to hospital. 'Sampling frames' commonly used to select controls include electoral registers, hospital admissions lists, general practitioner age-sex registers, hotel and reception guest lists, family members of cases, neighbors of cases, acquaintances nominated by cases, and persons investigated by the laboratory, but who were negative for the disease in question. When only a few cases are identified the statistical power of the study can be increased by increasing the number of controls per case up to five before the efficiency of the study falls.

Interpretation of differences in the proportions of cases and controls with a particular variable must take into account the possible effect of confounding factors. A confounding factor is one that is not the source of infection but is associated both with the cases and independently with the suspected source. The association with the occurrence of disease may lead to a misinterpretation of the source of the infection. When

confounding factors can be reasonably predicted they may be excluded by selecting controls that are matched to cases for exposure to those factors. For example, in the first recognized outbreak of hemorrhagic colitis in the USA in 1982, interviews with cases suggested that food eaten at one fast-food restaurant chain were associated with illness. Since exposure to the particular restaurant chain depended upon the location of the restaurants, and probably also on age, controls were matched with cases for neighborhood of residence and age. A significant association between illness and the restaurant chain was found and subsequently frozen hamburger meat from one restaurant yielded the causative organism *Escherichia coli* O:157 H:7 (Riley et al. 1983).

One development of case-control methodology made possible by laboratory typing techniques is case–case comparison to study causation of common infectious diseases (McCarthy and Giesecke 1999). Cases with the same disease can be divided into etiologically meaningful subgroups by subtyping the pathogen. Cases with one organism subtype are then compared with cases with a different subtype of the same organism. This removes several biases since both groups are drawn from the same population and no differential recall of exposures should occur. For example, a comparison of cases of *Campylobacter coli* infection with cases of *C. jejuni* infection from standardized, population-based sentinel surveillance information in England and Wales found that persons with *C. coli* infection were more likely to have drunk bottled water and were more likely to have eaten paté (Gillespie et al. 2002). Similar studies have compared cases of antibiotic-resistant and antibiotic-sensitive infection in order to identify risk factors for antibiotic resistance (Smith et al. 1999).

The major drawback of case-control studies is that accurate and complete data may not be available retrospectively. Medical records are notoriously incomplete and the recall of patients may be faulty. The latter problem is lessened in acute incidents, because there is usually little delay between the event and the interview. A particular problem is that of 'rumination bias'; because of their illness, sufferers will have gone over in their minds possible exposures and recall may be biased by their own preconceptions or by speculation in the press or other 'media'. Cases may also have been interviewed on many occasions; as well as promoting a more detailed recall, this may introduce bias from suggestions made by interviewers.

STATISTICAL ANALYSIS

In both cohort and case-control studies the basic analysis is made by a comparison of proportions. The data can be presented in a contingency table (Table 1).

Table 1 *Contingency table for cohort and case-control studies*

	Case	Not case	Total
Exposed	*a*	*b*	*a+b*
Not exposed	*c*	*d*	*c+d*
Total	*a+c*	*b+d*	*a+b+c+d*

In cohort studies the ratio $a/a + b$ is the attack rate in the exposed. The ratio $[a/(a + b)]:[c/(c + d)]$ is the ratio of the attack rates in the exposed and the unexposed and is called the relative risk. The size of the relative risk is an indication of the causative role of the factor concerned. In case-control studies there are usually no denominators from which risks can be estimated and it is necessary to work with the 'odds' of infection or exposure. The odds of a case having been exposed are a/c and the odds of a control having been exposed are b/d. The odds ratio, ad/bc, or crossproduct ratio, is a very useful measure of association. It approximates to the relative risk when the disease is rare. If there is no association between exposure and infection, the odds ratio will be unity.

In both cohort and case-control studies, dose response effects can be examined if data on different levels of exposure are collected. If the relative risk or odds ratio increases with increasing exposure, the strength of the evidence to determine causality is greatly enhanced. Dose response may be the only way of showing an association between exposure and disease if the exposure is universal (e.g. water consumption).

In analytical studies it is desirable that confidence intervals are presented together with the relative risk or odds ratio, rather than depending solely on p values. The p value is the probability of obtaining a difference between the proportion of cases and non-cases who are exposed, which is as large or larger than that observed in the study if there is no association between disease and exposure. The p value depends not only on the size of the effect but also on the sample size. A study may fail to show an odds ratio or relative risk significantly greater than unity even when a real difference exists because the study size is too small (type II error). Analysis of data sets usually begins by looking at exposure variables one at a time (univariate analysis). Associations between variables and the outcome measures may be causal or they may be due to shared associations with another variable, such as age or sex, known as a confounding variable. The latter can be investigated by stratified analysis in which associations between exposure and disease are examined within subcategories of the confounding variable. The Mantel–Haenszel method is frequently used and logistic regression modelling methods are increasingly used. When matched studies are performed the matching should be preserved in analysis and McNemar's test and the exact binominal probability should be calculated in place of χ^2 and Fisher's exact test. For further discussion of statistical methods see Breslow and Day (1980, 1987) and Altman (1991).

EPIDEMIOLOGICAL SURVEILLANCE

Surveillance needs to be distinguished from research. The former focuses on problem detection and characteristics, whereas research is mainly to do with hypothesis testing. Surveillance systems generate hypotheses and should not be expected to give detailed answers to research questions. Surveillance data provide information for action and as such should stimulate investigation. Emphasis has to be on speed of detection of a potential problem, rather than full and accurate documentation. Consequently, great care has to be exercised in interpreting surveillance statistics. Surveillance systems by definition require ongoing collection of data and consequently rely on minimal data which are often incomplete. National surveillance systems have often gone into decline because data collection has been driven by a desire for full documentation rather than the overriding requirements of timeliness and sensitivity to trends.

One of the earliest recorded surveillance programs was developed in the City of London in the sixteenth and seventeenth centuries to detect the appearance of plague, so that the City administration could decide when to close the theaters of the City to limit the assembly of large crowds of people, and the Royal Court could be advised if and when it was desirable to leave London to escape the disease. The parish clerks of the City were responsible for data collection; each parish appointed two lay searchers to ascertain burials of plague victims, which were then recorded by the clerks along with other burials in the parish burial registers. These data were summated each week by the parish clerks in returns to the Warden of the Hall of Parish Clerks, who then prepared a statistical tabulation of burials by parish. This was published in a weekly bulletin, the 'Bill of Mortality', together with information on the total plague burials compared with the previous week and the number of parishes affected by plague and the number free of the disease (Wilson 1927). The long-term trends in burials in London derived from these Bills of Mortality were studied in 1662 by John Graunt, a City draper, who assessed the validity of the data and demonstrated a higher mortality in towns than in the country by comparing London with Romsey in Hampshire, and drew attention to the high mortality in young children. Greenwood (1948) regarded John Graunt and William Petty, with whom Graunt worked, as the founders of present-day medical statistics.

Thacker and Berkelman (1988) wrote of the USA that: the 'basic elements of surveillance were present in Rhode Island in 1741 when the colony passed an act requiring tavern keepers to report contagious diseases among their patrons. Two years later, the colony passed a law requiring the reporting of small pox, yellow fever and cholera.' Systematic reporting of disease began in the USA in 1874 in Massachusetts, when the State Board of Health introduced voluntary weekly reporting of disease by physicians using a standard postcard.

In the UK, the need for more accurate and complete mortality data led to the introduction of medical certification of death and the civil registration of births, marriages, and deaths in 1836. The General Register Office for England and Wales was established in London, later known as the Office of Population Censuses and Surveys (OPCS) (Nissel 1987) and in 1996 it became part of the Office for National Statistics (ONS). Similar national register offices exist in the other countries of the UK. William Farr, the first Compiler of Abstracts (medical statistician) at the General Register Office, during his 41 years in office, initiated the present international classification of causes of death and developed further the surveillance of communicable disease, establishing a method of influenza surveillance that remains in use today. Dr John Simon, the first medical officer to the Local Government Board (Chief Medical Officer), said of William Farr: 'Eminently he was the man to bring into statistical relief, and to make intelligible to the common mind, whatever broad lessons were latent in the life-and-death registers of that great counting house . . .' (the General Register Office). This provision of readily comprehensible information to those who need it for prompt action remains a crucial component of surveillance.

Surveillance has now assumed even greater importance because of the increased threat of national and international spread of infections arising from the escalating speed, distance, and volume of human travel and the expanding national and international distribution of foodstuffs and other materials which may carry pathogenic organisms as well as from the threat of deliberate release (Lederberg et al. 1992). For example, surveillance may be the only means of detecting outbreaks when the victims have traveled during the incubation period from the place of exposure to many different destinations, or when the vehicle of infection is widely distributed geographically and sometimes also in time. In the face of this threat, national and international surveillance of communicable disease was revived and developed beginning in the 1950s (Langmuir 1963; Raska 1966). More recently, it has been appreciated that increasing human social, technical, environmental, and population change is likely to promote the evolution of new pathogens and facilitate the return of old diseases, now termed 'emerging and re-emerging infections', and that this requires increased surveillance on a global scale to ensure rapid detection, investigation, and control (Heymann and Rodier 1998).

The six main objectives of epidemiological surveillance for communicable disease are:

1 early detection of changes in disease pattern to enable rapid investigation and application of appropriate control measures

2 monitoring long-term trends in disease and infection, including serological surveillance, to assess the need for intervention and to predict future trends
3 determining the prevalent infections in a population so that clinicians may be alerted
4 collation of data about newly recognized or rare diseases at national or international level so that their epidemiology can be described and a basis for research is provided
5 evaluation of disease-control measures and preventive programs
6 planning and costing of health services for the prevention and control of communicable disease.

The method of surveillance remains similar to that of plague surveillance in the seventeenth century, namely:

- the systematic collection of data
- analysis of these data to produce statistics
- interpretation of the statistics to provide information
- timely distribution of this information in a readily assimilable form to all those who require it so that action can be taken
- continuing surveillance to evaluate the action.

The main principles of successful surveillance are simplicity, timeliness, accuracy, and regular analysis and reporting to those who provide data and to those who are responsible for control action (Teutsch and Elliott Churchill 2000). Surveillance is, by definition, an ongoing activity and can be sustained only when the burden placed on the data provider is light. Surveillance data should be limited to the minimum required to meet its specified objectives. Reporting methods should be simple and streamlined. Electronic data collection should be linked to electronic systems for dissemination of high quality surveillance information. For accuracy, surveillance data ideally require clear case definitions as have been developed by the Centers for Disease Control in the USA (Wharton et al. 1990).

Guidelines for the evaluation of surveillance systems have been proposed (Centers for Disease Control 2001). These include the following features:

- a description of the public health importance of the health event including incidence and prevalence, severity of disease as measured by mortality rates and case fatality rates, and preventability
- a description of the system including the objectives, the population under surveillance, case definitions, a flow chart of data collection, details of data transfer, data analysis, and dissemination of information
- a measure of the usefulness of the surveillance system including decisions and actions taken as a result of the information generated
- evaluation of key attributes of the system including: simplicity, flexibility, acceptability, sensitivity, predictive value positive, respresentativeness, and timeliness
- costs of the system.

Data-collection systems

Surveillance data may be sought actively or acquired passively by making use of routinely generated data.

Passive data-collection systems are based upon clinical or microbiological diagnoses which often do not have precise definitions and despite the absence of case definitions, these are invaluable for detecting episodes or cases for further study. For example, in all countries in the UK, cases of typhoid and paratyphoid fevers are detected nationally by statutory notifications, laboratory reports, and referral of cultures of the organisms for identification to the Health Protection Agency (HPA), formerly the Public Health Laboratory Service (PHLS). These three data sources are then linked (Wall et al. 1996). Further active enquiries are made by questionnaire to find out the country where the infection was acquired and possible sources of infection, so that preventive action may be taken. Similarly, cases of Legionnaires' disease are detected by laboratory and incident reports and subsequent active enquiries made, nationally and internationally, to discover cases associated with a common environmental source of infection, so that control measures can be quickly applied.

There is also a surveillance system for general outbreaks of infectious intestinal disease introduced in 1992 by the HPA Communicable Disease Surveillance Center (CDSC). This excludes family outbreaks affecting members of the same private residence only. The CDSC is made aware of outbreaks from laboratory reports, consultants in communicable disease control (CCDC), environmental health officers, and others. Outbreaks are then followed up using a standard request form which documents basic detail which is completed by the local investigator. Participation in the surveillance scheme is entirely voluntary (Wall et al. 1996).

Most active data-collecting systems are based on carefully designed standard case definitions. For example, the surveillance of certain rare childhood disorders, including Reye's syndrome, in the UK is maintained by the British Paediatric Surveillance Unit (BPSU), by monthly mailing of pediatricians to detect cases, followed by subsequent detailed clinical and epidemiological enquiry. These data are then assessed to ensure that all cases meet the standard case definitions before being analyzed to describe the epidemiology of the diseases (Verity and Preece 2002). A unit, similar to the BPSU, was created in 1994 for the active surveillance of neurological disease, the British Neurological Surveillance Unit. A clinical reporting system, set up in 1982 for surveillance of the AIDS epidemic, relies partly on the passive reporting of clinical cases, deaths, and laboratory data for the detection of cases and partly on the active collection of data when these were incomplete. The cases are then scrutinized to ensure that they meet the internationally agreed case definition so that

the changing epidemiology of the syndrome can be accurately described (PHLS AIDS Centre 1991).

MORTALITY DATA

Mortality data on communicable diseases have limited use because they do not usually cause death. However, they can be made available quickly, are usually accurate, and probably nearly complete. They have been used in the surveillance of influenza since the epidemic of 1847, now in combination with morbidity data from general practitioners and laboratory reports (Tillett and Spencer 1982), and in the surveillance of AIDS (McCormick 1994). The death entry is a public document and this may sometimes deter the doctor from entering the correct diagnosis on the death certificate, for example in deaths due to syphilis or AIDS, although the doctor may subsequently provide further information about a death in confidence, after the death entry has been completed.

STATUTORY NOTIFICATION

Notification of infectious disease was first introduced in Huddersfield in 1876 by local act of Parliament; other local authorities followed and in 1899 it became mandatory throughout England and Wales. Weekly summaries of these data began in 1910 and were first published in 1922. The Public Health (Control of Disease) Act 1984, Section 11, states 'if a registered medical practitioner becomes aware, or suspects, that a patient whom he is attending . . . is suffering from a notifiable disease' he/she shall notify forthwith the proper officer of the local authority (usually the CCDC). The CCDC in turn sends each week a return of the number of notifications received in the preceding 7 days to the ONS (except leprosy which is reported in strict confidence to CDSC). Weekly summaries of these data are available on the HPA website and are published electronically by CDSC in the weekly *Communicable Disease Report* (CDR). The data are later corrected and quarterly and annual summaries created. Similar systems operate in Scotland and Northern Ireland. The chief advantages of these data are that they are available quickly, they relate to defined populations so that rates by age and sex can be calculated, and they provide an invaluable means of monitoring trends for diseases that are not often confirmed in the laboratory, for example whooping cough and mumps. The defects of the data are that the clinical diagnosis may not always be correct; the diagnosis may vary between clinicians especially because there are no case definitions (except for ophthalmia neonatorum and food poisoning); under-notification frequently occurs and may vary from place to place and at different times (Doyle et al. 2002). These deficiencies can be partially overcome by training notifying clinicians and by regular feedback of local and national information, but it appears that neither the legal obligation to notify nor the payment of a fee promotes more complete notification (McCormick 1993).

In the USA, systems for the notification of selected diseases such as cholera, smallpox, plague, and yellow fever began to be introduced in 1878. By 1903 notification to local authorities for selected diseases was required in all states. In 1925 all states joined a national morbidity reporting system which was taken on after 1948 by the National Office of Vital Statistics which continued to produce weekly morbidity statistics. These reports have been developed as the *Morbidity and Mortality Weekly Report,* which since 1961 has been the responsibility of the Centers for Disease Control (CDC) in Atlanta. Currently, notifiable diseases are reported by states to CDC through the National Notifiable Diseases Surveillance System using the National Electronic Telecommunications System for Surveillance (Koo and Wetterhall 1996).

LABORATORY REPORTING OF MICROBIOLOGICAL DATA

The routine voluntary reporting of laboratory-diagnosed infections forms the core of communicable disease surveillance in England and Wales and also in Scotland, where a somewhat similar reporting system operates. This reporting system was originally developed by the PHLS in the 1940s and 1950s (Grant and Eke 1993) and comprises confidential electronic reporting each week by medical microbiologists to the director of CDSC in England and Wales and the Scottish Centre for Infection and Environmental Health (SCIEH) in Scotland each week of specified infections diagnosed in their laboratories. At CDSC, data are analyzed within a week of receipt to produce tables and line lists and to compile narrative reports for publication in the CDR. Statistics derived from these data are available on-line to staff in CDSC, and via the HPA website to CCDCs and medical microbiologists. The main benefits of laboratory reports are that they are very precise, in that they are based on laboratory-diagnosed infections and the fine typing of the infecting organisms; they often include clinical and epidemiological details; and they allow for free-text comment. Furthermore, the reporting system is flexible, so that any important, unusual or new infections can be reported, even though they were not necessarily included in the original reporting instructions. However, the reports have some drawbacks: they are limited to infections in which there is a suitable laboratory test; infections which are easily diagnosed clinically tend to be poorly covered; and the reports are not population based, that is the data do not usually have a population denominator, so that incidence rates cannot be calculated. Moreover, as with all routine morbidity reporting systems, the data are incomplete, not all laboratories report, and the completeness of the reports received may vary between laboratories and over time, so that trends are sometimes difficult to interpret.

In order to gain a better appreciation of the true incidence of gastrointestinal infections, a national study, the study of Infectious Intestinal Disease (IID) in England was commissioned by the Department of Health in 1990 (Wheeler et al. 1999; Food Standards Agency 2000). This provides the best data to date of the true incidence of enteric pathogens in the country. The objectives of the study were: first, to estimate incidence and etiology of intestinal infectious disease in people presenting to their general practitioners and from whom stool specimens are routinely sent for laboratory examination; second, to compare these data with the data from the national reporting surveillance system; and third, to estimate the prevalence of asymptomatic infection with these agents. Seventy practices were selected to be representative of the socioeconomic characteristics of the area and cases of infectious intestinal disease were defined as persons with loose stools or significant vomiting lasting less than 2 weeks in the absence of a known noninfectious cause and preceded by a symptom-free period of 3 weeks. Vomiting was considered significant if it occurred more than once in the 24-h period and if it incapacitated the case or was accompanied by other symptoms such as cramps or fever. One component of the study was to draw at random a cohort of people registered with the 70 GPs, who were followed up for a period of 6 months. These volunteers agreed to fill out diary cards every week and return them to the GPs. These cards stated whether the person had suffered gastrointestinal (GI) illness or not. If someone developed an illness, a stool sample was submitted.

Of particular interest in this study was the estimate of the carriage of potential pathogens in otherwise healthy people. Ten out of the 2 264 controls (0.4 percent) were found to be excreting *Salmonella*, 16 out of the 2 264 (0.7 percent) were excreting *Campylobacter*, but none out of 2 264 were excreting *E. coli* 0157. These data confirm that verotoxin-producing *E. coli* are a rare infection in the UK at the moment.

The IID study was also able to quantify the reporting pyramid referred to above using the cohort component of the study. It was estimated that for every case the IID reported to the CDSC, six patients were investigated by routine laboratory tests, 23 presented with GI symptoms to their GP, and there were 136 actual cases in the community. For *Salmonella* cases, however, the ratios were much smaller. For every case reported to CDSC, it was estimated that there were 2.3 cases presenting to their GP and 3.2 actual cases in the community.

GENERAL PRACTICE REPORTING OF CLINICAL DATA

Morbidity data from general practice were studied first in 1955, following which several national morbidity studies have taken place, the last in 1991–1992 (McCormick et al. 1995). Continuously collected clinical data from general practice, which is more useful in communicable disease surveillance, first became available in 1966 when the Royal College of General Practitioners (RCGP) set up a reporting system based on first consultations in a limited number of volunteer practices (Fleming 1999). In 2003 there were 73 participating general practices serving a population of about 615 000 people providing weekly data to the RCGP Research Unit in Birmingham for analysis. These weekly analyses are then sent to the ONS, the CDSC, the Department of Health (DoH), and other organizations concerned with national surveillance. They are published annually by the RCGP Research Unit in the annual reports of the unit. Analogous general practitioner reporting schemes operate in Wales (Palmer and Smith 1991) and some other parts of the UK. These general practitioner reporting systems act primarily as early warning systems providing data rapidly within 10 days of reporting and have the advantages that the data are related to defined practice populations and are unique for some common diseases which are not notifiable and for which laboratory tests are not usually performed, such as chickenpox, herpes zoster, and infectious mononucleosis (Fleming et al. 2002) (see Table 2). In the RCGP system, guidelines to diagnosis are provided and in the Welsh system a set of standard case definitions, but the precise definition of an infection is less important than the speedy recognition of an emerging outbreak which may require prompt investigation. However, there are some deficiencies: reporting may not always be complete; the population covered may not be representative geographically or demographically of the whole country and is too small for the surveillance of less common diseases (Harcourt et al. 2004).

REPORTS OF SEXUALLY TRANSMITTED DISEASES

Legislation in the nineteenth and early twentieth centuries required the registration, regular examination and, if necessary, detention of prostitutes, and compulsory admission to hospital for other sufferers from venereal disease (VD) was recommended. However, when a national VD service came into being in 1916, these legal powers were discontinued and a free confidential service for diagnosis and treatment was established at VD clinics, now genitourinary medicine (GUM) clinics. At the same time, a system of quarterly clinic returns began, providing the number of new episodes of specified infections by gender and for some diseases in age groups, which, with variations and additions, has continued ever since. Sexually transmitted infections, including AIDS, have not been made statutorily notifiable in the UK because of fears that a legal obligation to report individual patient data might lead to some individuals concealing their infections, consequently hindering the control of these infections. The clinic returns are analyzed by the UK departments of health and are collated by CDSC and SCIEH; annual and periodic

Table 2 *The main routine data-collecting systems*

Disease	Data collecting system				
	Death registration	Statutory notification	Laboratory reports	RCGP reports	GUM clinic reports
Anthrax		++	+		
Brucellosis			++		
Chickenpox	+		+	++

reviews of trends are published, the most recent for the decade 1991–2001 (PHLS, DHSS & PS and Scottish ISD(D)5 Collaborative Group 2001). The clinic returns provide data that are probably accurate, being based on specialist clinical diagnosis, often supported by laboratory tests, are unlikely to vary between clinics and over time, and provide a unique set of data extending over nearly three-quarters of a century for some infections. However, the reports record episodes of infection rather than patients, are incomplete because they do not include patients treated outside GUM clinics, and the proportion of patients treated outside the clinics is unknown and may vary by diagnosis, between clinics and over time.

HOSPITAL DATA

Data from a 10 percent sample of hospital discharges and deaths were available from 1955 to 1985, but had limited use in communicable disease surveillance because the data did not become available until about 2 years after collection (Ashley et al. 1991). In 1995, these data were replaced by Hospital Episode Statistics which are currently being assessed for their possible value in communicable disease surveillance. Paget (1897) in his book *Wasted Records of Disease*, referring to hospital records, commented: 'At present these records of disease are rarely utilized for public purposes, and they represent in their present circumstances little more than so much waste of time, material, and intelligence.' Over a century later, a satisfactory method of capturing these data for the surveillance of communicable diseases and other acute diseases has still to be found.

ROUTINE SEROLOGICAL SURVEILLANCE

In 1990 a serological study to measure the spread of HIV infection in the population was begun; it has continued since and become a routine surveillance system. Samples from sera collected for clinical purposes are unlinked from personal identifiers but remain linked to epidemiological information; sera remaining unused

are then tested for HIV infection. This Unlinked Anonymous Prevalence Monitoring Programme has since been extended to include viral hepatitis. The data have helped identify a continuing high rate of transmission among homosexual and bisexual men, and increased hepatitis C transmission in injecting drug users (Report 2002).

OTHER ROUTINE DATA-COLLECTING SYSTEMS

Work-absence data have been used in the surveillance of influenza, but surveillance is now based principally on mortality data, laboratory reports, and general practitioner reports. CCDCs report voluntarily to the CDSC outbreaks occurring in their districts and are required to report serious outbreaks; these reports are usually of food-borne diseases, notably salmonellosis, and provide supplementary data for surveillance of these diseases.

More recently, data from NHS Direct, a national telephone helpline service for health-related enquiries operated by nurses in the UK, have been explored for their potential use in communicable disease surveillance. NHS Direct data on calls for 'influenza-like illness' have been found to correlate well with other routinely available influenza surveillance data (Harcourt et al. 2001). Despite its limitations, the timeliness and population coverage of the service make it a valuable potential source of data for diseases such as influenza or gastrointestinal illness that are mostly treated by primary care (Cooper et al. 2003).

Action consequent on surveillance

Changes in numbers of reports were hitherto usually discovered by examining the data in either numerical or graphical form, but statistical and computer techniques are now often used to assist in the detection of significant variations from previously recorded experience (Tillett and Spencer 1982; Farrington and Beale 1993). Such variations may indicate changes in the incidence of disease, but they may also result from changing interest of disease, altered diagnostic techniques or reporting methods, or fluctuations in the number of microbiologists, laboratories, clinicians, practices, or clinics participating in the reporting system. It is usual, therefore, to compare the data from all the relevant data-collecting systems to validate the observed trends. Often, especially if there is a rapid increase in reports, field investigation is necessary to substantiate an increase and determine its cause.

Routine, regular, and systematic dissemination of information to the providers of the data and to disease control authorities is essential for successful surveillance (Langmuir 1963). In the United Kingdom this is maintained through the weekly CDR and the monthly *Communicable Disease and Public Health*, which are available without charge to professional staff concerned with the control of communicable disease. These bulletins contain narrative reports of newly identified or suspected outbreaks of disease, reviews of prevalent communicable diseases and related topics as well as numerical data on certain organisms, notifiable diseases, and general practitioner reports. More extensive reviews are published in quarterly reviews, annual reports, and in the medical press. Sometimes when an acute episode of infection is identified, more rapid transmission of information electronically, by phone, or facsimile is required.

The uses of epidemiological surveillance may be illustrated by examples that refer to its main objectives.

EARLY DETECTION FOR RAPID CONTROL

In November 2000, an outbreak detection algorithm identified a cluster of 12 cases with *Salmonella* Enteritidis phage type 4b in data from the National Reference Center for Salmonella at the National Institute of Public Health and the Environment (RIVM) in The Netherlands. A rapid descriptive epidemiological study identified chicken, eggs, or bean sprouts as the possible vehicles of infection. These hypotheses were tested by a case-control study which showed a statistically significant association between infection and eating bean sprouts. Two days after the cluster was detected, the company that produced the sprouts voluntarily took several measures including intensified testing, removal of the raw materials from which the contaminated bean sprouts were grown, and disinfection of the factory premises. No further cases of *Salmonella* Enteritidis phage type 4b were reported (Van Duynhoven et al. 2002).

ASSESSING THE NEED FOR INTERVENTION

Notifications of meningococcal disease increased in UK in the early 1990s with a much higher proportion being notified as meningococcal septicemia. Laboratory surveillance also indicated that there was an increase in the proportion of cases due to *Neisseria meningitidis* serogroup C, particularly serotype C2a infections (Ramsay et al. 1997). In response to this, an enhanced surveillance system for meningococcal disease was begun in January 1998 that combined data from statutory notifications, routine laboratory reporting, and the PHLS Meningococcal Reference Unit (Davison et al. 2002a). The greatest burden of disease was in young children and teenagers, and there was some evidence that sequelae were more common than occurred following serogroup B meningococcal disease. This information was provided to the Joint Committee on Vaccination and Immunisation and provided the basis for a decision to introduce a national meningococcal serogroup C conjugate vaccination program in the UK in November 1999, the first country in the world to do so (Davison et al. 2002b).

The vaccine was incorporated into the routine infant immunization schedule and was offered to all under 18 year olds in a catch-up campaign. The vaccine was well accepted with coverage around 90 percent in infants and 85 percent in schoolchildren up to the age of 14 years. The incidence of serogroup C meningococcal disease in the targeted age groups fell by 80 percent in 2000/2001, and the number of deaths in laboratory-confirmed cases under 20 years of age fell from 78 to eight between 1998/1999 and 2000/2001 (Trotter et al. 2002). The incidence of serogroup B disease increased slightly over this same time period, but the reduction in serogroup C disease has been sustained.

DETERMINING PREVALENT INFECTIONS AS AN AID TO CLINICAL CARE

Following the introduction of methicillin-resistant *Staphylococcus aureus* (MRSA) into Wales in the early 1990s, continuous total population surveillance was introduced. The objectives were to gain an understanding of the extent of MRSA, to describe variations in incidence, to measure the burden of disease, and to identify possible risk factors for infection (Morgan et al. 1999). All first isolates of MRSA from both hospital and community settings and all isolates of methicillin-sensitive *Staphylococcus aureus* (MSSA) from blood or cerebrospinal fluid (CSF) were reported electronically by microbiology laboratories, and the data analyzed at CDSC (Wales). The incidence of MRSA was found to be highest in older patients and in men. Blood and CSF isolates were more likely to come from postsurgical patients. The majority of isolates were resistant to at least two antibiotics in addition to methicillin, most frequently erythromycin and the fluoroquinolones. The surveillance system has thus allowed a simple and intelligible picture of the MRSA problem to be determined, and this information has been fed back to hospitals to assist decisions on infection control.

Important developments in communicable disease may be brought to the attention of clinicians when required, by Chief Medical Officer letters, by reports of specialist associations, and by the medical press. The use of electronic communication is increasingly giving clinicians rapid access to communicable disease surveillance information via the Internet.

DETECTING NEW OR RARE DISEASES FOR STUDY

The surveillance of Reye's syndrome began in 1981. This showed that the annual incidence varied between 0.3 and 0.6 per 100 000 in the British Isles with the highest rate in Northern Ireland. No clear seasonal peaks were seen, but 59 percent of patients had an onset of disease in autumn or winter. The median age was 14 years and the sex distribution equal. The national collection of data on cases that met the standard case definition enabled an analytical study to be made of risk factors in the disease. This suggested an association with the use of aspirin, similar to that seen previously in the USA (Starko et al. 1980), and led to the withdrawal of pediatric aspirin preparations and cessation of the general use of aspirin in childhood in 1986. The surveillance scheme continued and demonstrated a decline in the number of cases in subsequent years despite more active data collection (Newton and Hall 1993).

EVALUATION OF PREVENTIVE PROGRAMS

In October 1992, *Haemophilus influenzae* type b (Hib) conjugate vaccine was introduced to infants in the United Kingdom with a catch-up programme for those aged under 4 years. An enhanced prospective survey using data from laboratory surveillance showed that during the prevaccination period the majority of cases of invasive Hib occurred in children under 5 years of age and that it was the most common cause of meningitis in this age group. After the introduction of routine Hib immunization, there was a 16-fold reduction in the annual attack rate of invasive Hib disease recorded in children under 5 years of age, but no decrease in the number of infections caused by other serotypes (Slack et al. 1998).

However, although the rate of invasive Hib disease initially decreased dramatically, surveillance showed a resurgence from 1999 onwards. To identify possible reasons for this increase, the effectiveness of the vaccine was investigated. Vaccine efficacy was found to be lower in children vaccinated during infancy, compared with those who were vaccinated during the catch-up campaign, to decline with time since vaccination and to be lower in children born during 2000–2002 (Ramsay et al. 2003). Lower efficacy during 2000–2002 was subsequently found by means of a case-control study to be due to the introduction of combination vaccines that contained acellular pertussis (DTaP-Hib) (McVernon et al. 2003). In February 2003, the Department of Health announced a second catch-up campaign offering all children between 6 months and 4 years a further dose of Hib vaccine (Trotter et al. 2003).

PLANNING AND COSTING OF HEALTH SERVICES

Surveillance data on AIDS and HIV infection have been used to make future projections of the likely numbers of cases of AIDS and severe HIV disease for planning purposes (Report 1996). By employing surveillance data on salmonellosis Sockett (1995) has assessed the costs of the disease and estimated the cost–benefits of preventive measures.

Surveillance of immunization programs

After licencing and general release of a vaccine, continuing surveillance is necessary, not only to demonstrate the effect of the immunization programs on disease inci-

dence, but also to monitor any subsequent changes in vaccine efficacy under field conditions, to identify groups of susceptible subjects, and to detect unsuspected, rare or new vaccine reactions (Begg and Miller 1990). The main objectives of surveillance of immunization programs are, therefore, the continual measurement of efficacy, safety, and uptake of vaccines.

VACCINE EFFICACY

Potency testing

In the UK, vaccine manufacturers are required by the Medicines Act 1976 to submit to the Medicines and Healthcare products Regulatory Agency (MHRA) a detailed application for licencing of all new vaccines. These applications include information about the quality assurance laboratory tests that they will subsequently carry out on all batches of vaccines that they produce before they are released, to ensure they meet agreed standards of efficacy and safety and conform with World Health Organization (WHO) and European Union standards. The National Institute of Biological Standards and Control (NIBSC), acting on behalf of MHRA, receives samples of all batches before release and verifies that they meet the required standards. After release, samples taken from the field are sometimes retested by NIBSC, for example, in the event of apparent vaccine failure, vaccine-associated disease or problems with the vaccine cold chain. In warm climates special measures are required to ensure the stability of vaccines, particularly live virus vaccines, because of their sensitivity to environmental conditions, and cold-chain monitors (temperature-sensitive color cards) are usually included in vaccine packs to monitor these circumstances. These are now also used in many temperate areas to ensure careful attention to vaccine handling and storage.

Causative organisms

Organisms that cause vaccine preventable diseases need to be continually monitored as they may undergo modifications in antigenic structure that may render vaccines less effective. For example, because of continual small antigenic changes in the influenza A virus (antigenic drift) and occasional larger changes (antigenic shift), viral isolates from all parts of the world are collected and studied in WHO collaborating centers, so that the most appropriate strains may be selected for vaccine production (Pereira 1979). Organisms may also undergo changes in the prevalence of different serotypes. For example, the efficacy of whooping cough vaccine appeared to decrease in the 1960s and was found to be due to a change in the prevalent serotypes of *B. pertussis* (Preston 1965); it was subsequently corrected by the inclusion of the new serotypes in the vaccine.

Serological surveillance

Serological studies provide valuable information about the duration of vaccine-induced immunity in individuals and the extent of immunity in the population. For example, serological surveillance in England and Wales between 1986 and 1991 showed that the proportion of school-aged children who were susceptible to measles was increasing following the introduction of measles, mumps, and rubella (MMR) vaccination in 1988 and, using mathematical models, a major epidemic was predicted in the mid-1990s (Ramsay et al. 1994). A national vaccination program for school-aged children ensued in November 1994 and an epidemic was averted.

Epidemiological studies

Vaccine efficacy (VE) can be calculated from the following equation (where ARu is attack rate in the unvaccinated and ARv is attack rate in the vaccinated):

$$\mathrm{VE} = \frac{(\mathrm{ARu} - \mathrm{ARv})}{\mathrm{ARu}} \times 100$$

The epidemiological techniques for measuring vaccine efficacy in the field were reviewed by Orenstein et al. (1985). There are five main methods:

1. Screening. If a vaccine has a 90 percent efficacy, an attack rate of over 10 percent in vaccinated subjects indicates the need for investigation. Farrington (1993) discusses the method in more detail.
2. Outbreak investigation. The assumption which must be satisfied in the above equation is that both vaccinated and unvaccinated subjects have had equal exposure to infection, an assumption which is likely to be satisfied in outbreaks in confined populations when the attack rate is high (e.g. in institutional outbreaks of measles where case ascrtainment will also probably be complete and immunization records easily available) (Haber et al. 1995). The method can also be applied in community-wide outbreaks in a defined population or in samples of that population.
3. Secondary attack rates in households. This method has been used to determine the efficacy of varicella vaccine, because here again the contacts of the index cases in households are likely to have an equal exposure to infection. By adding together the data from several households, sufficient numbers become available for analysis (Vessey et al. 2001).
4. Routine data-collecting systems. These can be used to estimate vaccine efficacy if the data can be linked with immunization histories. The poportion of cases in the vaccinated (PCV) is related to VE and the proportion of the population vacinated (PPV). Using a variation of the formula:

$$\mathrm{PCV} = \frac{\mathrm{PPV} - (\mathrm{PPV} \times \mathrm{VE})}{1 - (\mathrm{PPV} \times \mathrm{VE})}$$

Orenstein et al. (1985) showed that by means of this formula it was possible to estimate vaccine efficacy when the attack rates in vaccinated and in unvaccinated individuals were not known (Figure 6). For example, analysis of routine surveillance data on hepatitis A infections linked to immunization histories demonstrated the efficacy of routine hepatitis A vaccination to control the disease in a community with recurrent epidemics (Averhoff et al. 2001).

5 Case-control and cohort studies (Smith et al. 1984). Case-control methods have been used to determine measles and pertussis vaccine efficacy by comparing the immunization status of notified cases with that of children on the child-health computer file, which is available in most parts of the UK (Clarkson and Fine 1987).

VACCINE SAFETY

Common, local or systemic vaccine reactions are likely to be identified in large-scale clinical trials before the introduction of vaccines into general use. Post-licensure data on vaccine reactions are collected both passively and actively in the UK. The principal passive data-collecting system relies on medical practitioners reporting suspected reactions following immunization to the Committee on the Safety of Medicines, using specially designed yellow cards which are available in everyedition of the *British National Formulary*. These reports are reviewed regularly by the Joint Committee on Vaccination and Immunization. Other sources of data are complaints to vaccine manufacturers and informal reports to NIBSC, CDSC, and the National Poisons Centres. Unfortunately, none of these passive data collecting systems normally involves the doctors reponsible for immunization, the immunization coordinators, and consequently they are liable to remain unaware of adverse reactions taking place locally in their immunization programs (Miller et al. 1998). Active data collection has been used in the surveillance of smallpox vaccine adverse events in civilians in the United States (Centers for Disease Control 2002) and in special studies of bacille Calmette-Guerin (BCG), measles, and MMR vaccines (Begg and Miller 1990).

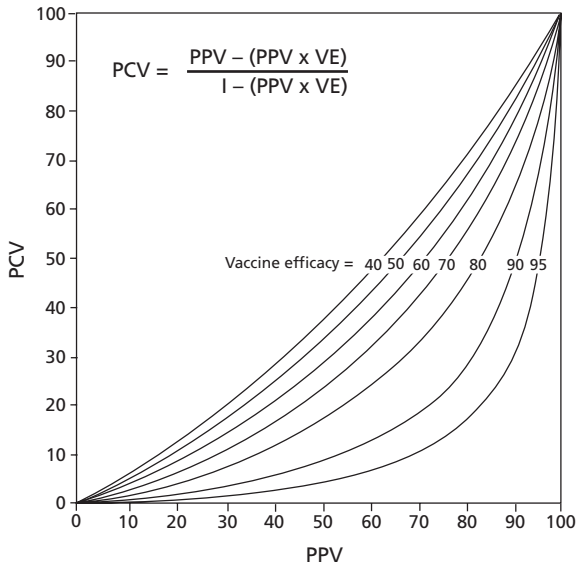

Figure 6 *Relationship between PCV and PPV*

Investigating whether an adverse event is causally related to immunization poses considerable difficulties. The following four methods have been developed:

1 Case clusters. When clusters of disease or reactions are detected in apparent association with imunization, field investigation may discover the cause and lead to prevention of a recurrence. For example, a cluster of cases of aseptic meningitis associated with measles/mumps/rubella vaccine in Nottingham UK, triggered an investigation that led to the withdrawal of Urabe strain mumps vaccine (Miller et al. 1993). Similarly, after a cluster of infant deaths due to severe metabolic acidosis following immunization was reported in a farming village in Egypt, investigations found that the deaths, and other previously unrecognized illness following immunization, were associated with excessive topical application of methanol as an antipyretic and anti-inflammatory agent following injections (Darwish et al. 2002). The practice was subsequently stopped.

2 Etiological investigations. These may detect the agent of a live vaccine in the lesion which has followed immunization, for example, the CSF in meningoencephalitis after mumps vaccination may be shown to contain vaccine virus (Maguire et al. 1991).

3 Case-control studies. The comparison of the vaccine histories of cases experiencing vaccine reactions with those of a control group, matched for age and sex, may reveal a temporal association between vaccination and the reaction, but this association may not be causal. For example, a strict case-control study showed an association between whooping cough immunization and serious acute neurological illness (Miller et al. 1981), but after several years of further studies and continuing debate it was concluded that this association was not causal (Griffith 1989). Cohort studies, comparing disease in a vaccinated group with that in an unvaccinated group, are not suitable for studying rare vaccine reactions because the incidence in the study population is likely to be too low to find significant differences between the two groups.

4 Case series analysis. Farrington et al. (1996) have described a method for estimating the incidence of clinical events after vaccination compared with a control period, based upon data from the cases alone, which may be used for monitoring vaccine safety when a vaccine is in widespread use. This method has the great advantage of reducing the need to follow up

large population cohorts or of selecting and investigating control groups. It has been used, for example, to investigate adverse events after pertussis and MMR vaccinations (Farrington and Pugh 1995) and a possible link between oral polio vaccine and intussusception (Andrews et al. 2001).

VACCINE UPTAKE

Vaccine uptake is measured by four main methods:

1. Vaccine usage gives a coarse measure of vaccine uptake. Despite being inaccurate because vaccine wastage and incomplete courses are not taken into account, the method enables major changes to be recognized quickly, which can then be investigated in the field. This method has been used to investigate variation in pneumococcal vaccine uptake between countries (Fedson 1998).
2. Repeated health surveys can also be used to estimate and monitor uptake. They are useful when data on individual immunization status is not readily available from medical data systems. An example is the Behavioral Risk Factor Surveillance System (BRFSS) used in the United States to estimate coverage of influenza and pneumococcal vaccines (Report 2003).
3. Calculated vaccine coverage gives a much more precise measure but requires accurate data on immunized individuals and up-to-date population denominators. An example is the Cover of Vaccination Evaluated Rapidly (COVER) program used in the UK to calculate uptake in the routine childhood immunization programme. Using a computerized national child-health register, quarterly cohorts of children are studied just after reaching the age of immunization to determine the numbers immunized. Quarterly uptake rates are calculated using the resident population denominators and the results made available quickly to immunization coordinators (Begg et al. 1989).
4. The WHO Expanded Programme of Immunization has developed a variety of techniques for rapid assessment of overall population vaccination coverage. Cluster sampling has been used to randomly select groups of children whose immunization histories are then recorded and used as an estimate of the vaccine uptake of the area sampled. Repeated sampling over time can reveal trends in uptake (Henderson and Sundaresan 1982). Lot quality assessment sampling is a method based on industrial techniques for quality control of manufactured products. It is a form of stratified sampling. Rather than check every item in a lot to determine the number of defective items, a sample of the lot is taken and a predetermined level of risk defined in order to decide whether to accept or reject the entire lot (Hoshaw-Woodward 2001). This method has been used to assess tetanus vaccine coverage in the WHO neonatal tetanus elimination campaign (Cotter et al. 2003).

THE INVESTIGATION OF OUTBREAKS

In the past, the detection of outbreaks of disease relied mainly on the appearance of groups of cases associated in time or place. With the advent of epidemiological surveillance it became possible to search actively for less apparent outbreaks and other variations in disease pattern, recently aided by the use of computer programs (Farrington and Beale 1993). The investigation of outbreaks, or indeed a single case, requires a systematic approach (Goodman et al. 1990) to achieve rapid and effective disease control. This can also be assisted by computer programs, for example, 'Epi-Info' produced by the Centers for Disease Control, Atlanta, now widely used throughout the world. The epidemiological methods used for this purpose were pioneered by John Snow in his famous study of cholera near Golden Square, London in 1854 (Snow 1855) and remain in use today. They may be considered under six main headings:

1. preliminary enquiry
2. management
3. identification of cases and collection and analysis of data
4. control
5. communication
6. further epidemiological and laboratory studies (Palmer and Swan 1991).

It is not always appropriate to follow this sequence of action; the order will depend upon the particular circumstances of an outbreak and often several of the steps are taken at the same time. There is a useful list of sources of information available in the UK for communicable disease control, designed particularly for CCDCs (Morgan et al. 1992). A detailed account of the methods of field investigation can be found in Gregg (2002).

Preliminary enquiry

The objects of the preliminary enquiry are:

- to confirm that there is in reality an outbreak
- to verify the provisional diagnosis of the disease
- to agree a case definition for epidemiological investigation
- to formulate tentative hypotheses of the source and spread of the infection and
- to initiate immediate control measures if required.

CONFIRMING THE OUTBREAK

An increase in the reported number of cases of a disease may not necessarily be caused by an outbreak, but could be due to changes in recognition or reporting. For example, the increase may be related to improved ascertainment of cases following the introduction of new or more sensitive diagnostic procedures, to the need to

detect as many cases as possible because of the availability of a new specific treatment, or to more extensive investigation of a disease because of special interests of new clinicians or microbiologists. Reporting may increase because of changes in the population size or structure, or as a consequence of improved data handling procedures such as computerization, or as a result of false positive laboratory or other tests, or because of the misinterpretation of the original data (Shears 1996).

CONFIRMING THE DIAGNOSIS

The clinical diagnosis can usually be established by a study of the case histories of a few affected persons. Laboratory tests are essential to confirm this in most infections, but epidemiological investigations should begin as soon as possible and not normally be delayed until the laboratory results become available.

CASE DEFINITION

A clear case definition should be agreed at this stage and applied consistently throughout the investigation by all investigators. This is of particular importance in a previously unrecognized disease or one in which there are no satisfactory confirmatory laboratory tests.

TENTATIVE HYPOTHESIS

The preliminary enquiry should include detailed interviews with a few of the affected persons, so that obvious common features may be identified quickly; for example, the association with a specific food, or contact with a particular person or place. Hypotheses can then be developed of the sources and mode of spread of the infection and a questionnaire designed to test these hypotheses in subsequent analytical tudies.

IMMEDIATE CONTROL

It may be possible in some circumstances to take immediate control measures based on the tentative hypothesis before this can be confirmed, so that further cases may be prevented. For example, in serious infections that spread from person to person, such as diphtheria, hepatitis B or poliomyelitis, as soon as the diagnosis is suspected it is necessary to identify individuals who may have been the source of infection so that they are isolated if appropriate, and to identify those who may have been exposed to infection so that they can be traced and given protection by vaccines or chemotherapy. If a common vehicle or source of infection is suspected, appropriate action should be taken to interrupt the spread and control the source.

Management of an incident

If the preliminary enquiry confirms that the outbreak is indeed real, an early decision should be made on the management of the investigation. Small outbreaks will usually be managed by the CCDC with the appropriate and usually essential assistance of a consultant microbiologist and an environmental health officer. In hospitals, an outbreak will usually be managed by the infection control doctor assisted by the infection control nurse (Hospital Infection Working Group 1995). The CCDC is obliged by the Public Health (Infectious Diseases) Regulations 1988 to inform the Chief Medical Officer for England, or for Wales as appropriate, and the CDSC of 'any serious outbreak of any disease' and of cases of disease subject to the International Health Regulations (meaning here cholera, plague, smallpox, and yellow fever) (see also Table 3). He/she should also report directly to CDSC any case of leprosy, malaria, or rabies contracted in Great Britain, and viral hemorrhagic fever. In serious incidents, that is large outbreaks, severe diseases, geographically widespread outbreaks, and those of public interest, an outbreak control team should be formed. This should include, in addition to the CCDC, a consultant medical microbiologist, a CDSC consultant epidemiologist, and a consultant physician in infection. Other agencies may also be involved, for example in suspected water-borne disease these may include the local water companies, river authorities, veterinary services, and the Department of the Environment, Food and Rural Affairs (DEFRA) (Report of the Group of Experts 1990). The control team will require an administrator or nonmedical epidemiologist to manage an 'incident room' where information on the outbreak should be collated and made available to those who require it. The control team should define the responsibilities of its members and allocate to one person the task of spokesperson for the press and other news media, often through the local authority, health authority, or DoH press officers. The control team should meet frequently until the acute incident is over when its tasks may be devolved to the local authorities, health authorities, and the CDSC.

Identification of cases, collection, and analysis of data

The cases first reported in an outbreak usually comprise only a small proportion of the total and may not be a representative sample. Investigation of these cases alone may be misleading for three main reasons:

1. in diseases spread from person to person, such as diphtheria, missed cases or carriers may be responsible for spreading the infection
2. in point-source outbreaks, such as those of Legionnaires' disease or food-borne diseases, the presenting cases may have come to light because of a chance association with a place or potential vehicle of infection
3. without knowing the population from which the cases have come, the denominator of 'persons at risk' is not

Table 3 *Statutorily notifiable diseases*

Notifiable diseases	
Under the Public Health (Control of Disease) Act 1984	
Cholera	Relapsing fever
Food poisoning	Smallpox
Plague	Typhus
Under the Public Health (Infectious Diseases) Regulations 1988	
Acute encephalitis	Ophthalmia neonatorum
Acute poliomyelitis	Paratyphoid fever
Anthrax	Rabies
Diphtheria	Rubella
Dysentery (amoebic and bacillary)	Scarlet fever
Leprosy	Tetanus
Leptospirosis	Tuberculosis
Malaria	Typhoid fever
Measles	Viral hemorrhagic fever
Meningitis	Viral hepatitis
Meningococcal septicemia (without meningitis)	Whooping cough
Mumps	Yellow fever

Notes: 'Viral hemorrhagic fever' means Argentine hemorrhagic fever (Junin), Bolivian hemorrhagic fever (Machupo), Chikungunya fever, Congo/Crimean hemorrhagic fever, dengue fever, Ebola virus disease, hemorrhagic fever with renal syndrome (Hantaan), Kyasanur forest disease, Lassa fever, Marburg disease, Omsk hemorrhagic fever, and Rift Valley disease.
There are minor differences in notifiable diseases in Scotland and Northern Ireland (see Ashley et al. 1991).
Some diseases are notifiable locally, for example, psittacosis in Cambridge.
AIDS is not statutorily notifiable, but clinicians report cases voluntarily, in strict confidence, to the directors of the CDSC in England and Wales and of the SCIEH in Scoland. Advice about reporting is available from these centers from genitourinary medicine physicians.

available to calculate attack rates and so determine whether or not a particular exposure was associated with an increased incidence of the disease.

Identification of the exposed population will enable thorough case finding to be accomplished, for example, by scrutinizing school or hotel registers, lists of institutional residents, pay-rolls, and other occupational records, nominal rolls of travelers, and lists of persons attending functions associated with the disease. If such studies are not possible, as is often the case in community outbreaks, case finding may be undertaken by reviewing routine mortality and morbidity data used for communicable disease surveillance, by individual household enquiry, and by special appeal to medical and lay persons through the press and other news media.

The aim of the enquiry will be to collect data from those affected and those at risk but not affected, by careful questionnaire. The data routinely sought from cases include name, date of birth, gender, occupation, recent travel, immunization history, date of onset of symptoms, description of the illness, and the names and addresses of the medical attendants. Other details will depend on the nature of the infection and possible modes of spread. The case data will then be analyzed by time, place, and person to determine the mode of spread, source of infection, and persons who may have been exposed. The date or time of onset of symptoms of cases should be plotted on a graph so that the type of epidemic curve can be recognized, and on a map to reveal the geographical distribution of the cases. Cases that do not conform to the time or geographical distribution may sometimes provide valuable evidence of the source of infection. For example, in John Snow's classic study of the outbreak of cholera near Golden Square, Soho, in 1854, a widow died of the disease in West Hampstead, several miles from Soho, and provided the most conclusive evidence of the source of infection because she had previously resided in Broad Street and had delivered to her daily a large bottle of water from her favourite supply, the Broad Street pump (Snow 1855). Comparisons of attack rates by age, gender, location, food history, and other appropriate parameters may provide evidence of the source and spread of infection which may then be confirmed by analytical epidemiological studies already described.

Control

Control measures may be directed towards the source of infection, the mode of transmission, people at risk, or a combination of these.

CONTROL OF THE SOURCE

The source may be human, animal, or environmental.

Human source

Infections derived from a human source can be controlled by the physical isolation of cases and carriers

and, if necessary, treatment until they are free from infection, provided that the cases and carriers are easily identified and carrier rates are low. For example, it is possible to control diphtheria and typhoid fever in this way because cases can be recognized clinically and confirmed by laboratory tests and because carrier rates are low and carriers can readily be detected microbiologically. In contrast, meningococcal infection is not susceptible to control by isolation because pharyngeal carrier rates in excess of 20 percent in the population are common during outbreaks and it is usually impractical to detect and isolate all the carriers. The method of physical isolation used depends upon the mode of spread and severity of the disease; for example, negative-pressure plastic isolators are used in the UK for the African viral hemorrhagic fevers, room isolation for diphtheria, and special precautions in the disposal of secretions and excretions (isolation by 'barrier nursing') in typhoid fever. Isolation of human sources of infection can also be accomplished in some diseases by 'ring immunization', that is, by encircling the case or carrier with a barrier of immune persons which blocks the spread of infection to susceptible people outside the 'ring'. This method was first used in Leicester in the nineteenth century and later throughout the UK for smallpox control; when modified and accompanied by meticulous surveillance worldwide it helped to achieve the eradication of the disease (Fenner et al. 1988). It has also been applied in the control of poliomyelitis by mass immunization and in measles by immunization of contacts in school and institutional outbreaks.

Animal source

When animals are the source of an infection, it is sometimes possible to control an outbreak by eradication of that source, for example, in ornithosis by slaughtering the birds and disinfecting the cages and premises. Rabies may be controlled by the destruction of rabid animals and of wild or stray animals that may harbor the virus, and by the muzzling of domestic dogs. Outbreaks of food-borne zoonoses are usually controlled by removing the vehicle of infection: eradication plays a major part in the long-term control of these zoonoses, for example, bovine tuberculosis and brucellosis.

Environmental source

The source of Legionnaires' disease and primary amoebic meningoencephalitis, both recognized in the 1970s, is water in the environment. Outbreaks of Legionnaires' disease are usually associated with water-cooling systems of air-conditioning plants, water-distribution systems in large buildings, or whirlpool spas. Primary amoebic meningoencephalitis is usually contracted from warm unchlorinated natural water sources, such as warm springs, sometimes used to supply swimming pools. Both these infections may be controlled by appropriate cleansing and disinfection. Other pathogens, mainly gram-negative bacteria, may contaminate the inanimate environment of man; for example, salmonellae are found on work surfaces, utensils and equipment in kitchens, and coliform organisms and pseudomonads on surfaces and equipment in hospitals. Control measures include appropriate cleansing, disinfection or sterilization of these environmental sources.

CONTROL OF SPREAD

Food- and water-borne infections can be curtailed by withdrawal from sale of the contaminated product or treatment of the product to render it safe, for example, the recall of a contaminated meat product (Macdonald and Drew 2000), and the pasteurization of a contaminated milk supply (Proctor and Brosch 1995).

Direct contact infections may be reduced by avoiding contact, for example, in cutaneous anthrax by not handling potentially contaminated animal products such as unsterilized bone meal.

Indirect contact infections, for example, staphylococcal infections in hospitals, may be reduced by strict aseptic techniques and meticulous hand washing, accompanied in the case of wound infection by the use of 'no touch' dressing techniques.

Fecal–oral spread, such as in bacillary dysentery and hepatitis A infection, may also be restricted by scrupulous attention to hand washing and by the careful and frequent disinfection of surfaces in lavatories and toilet areas.

Percutaneous spread by insects, such as in malaria, typhus, and yellow fever, may be controlled by vector destruction, protective clothing, and insect repellents. Infections spread by percutaneous inoculation, such as hepatitis B and HIV, may be prevented by measures to avoid accidental inoculation and the contamination of broken skin by infected blood or tissue fluids.

Air-borne spread may be limited by ventilation in buildings and in special circumstances the physical isolation of highly susceptible subjects.

CONTROL OF PERSONS AT RISK

It is sometimes possible to control disease by active or passive immunization or by chemoprophylaxis in persons exposed to risk. For example, active immunization against measles within 72 h of exposure may prevent the disease. Human immunoglobulins are commonly given for passive protection, for example, rabies immunoglobulin in addition to active immunization as part of post-exposure prophylaxis given as soon as possible after exposure, hepatitis B immunoglobulin in post-exposure prophylaxis after accidental inoculation injury and for infants of carrier mothers, and zoster immunoglobulin in the newborn and immunodeficient patients after expo-

sure to chickenpox. Chemoprophylaxis is offered to close contacts of cases of meningococcal disease, such as household contacts and children in the same class at school, and long-term chemoprophylaxis against pneumococcal infection is given to patients after splenectomy.

Communication

Accurate and timely information about an outbreak is of major importance, especially if the outbreak is of national interest and is receiving wide publicity. To achieve this, it is helpful for the CCDC to maintain a check list of authorities and individuals to be informed (Morgan et al. 1992). These would normally include the local consultant physician in infection, microbiologist, chief environmental health officer, and director of public health, but depending upon the type of outbreak might also include the local divisional veterinary officer, employment medical adviser, education officer, and clinicians in hospital and general practice, and similar persons in neighboring areas. In a major incident, national authorities including the HPA and its CDSC, the DoH, the Food Standards Agency (FSA), DEFRA, the Health and Safety Executive, and others may be involved. An initial written report should normally be completed within 24–48 h after the preliminary enquiry and circulated to all the authorities and individuals concerned. A final report suitable for publication should be produced at the end of the investigation and interim reports may be necessary if the investigation is complex or prolonged. In a major incident it may also be necessary for frequent bulletins of updated information to be issued by the spokesperson of the 'outbreak control team' from the 'incident room'.

Further epidemiological and microbiological studies

Analytical studies may be necessary to confirm the association of disease with a particular vehicle or source of infection. Often case-control studies are undertaken early in an enquiry because they can be accomplished quickly and cheaply, but more time-consuming cohort studies may be required to determine the relative risk so that the most cost-effective long-term control measures can be implemented.

An outbreak may suggest a previously unknown source or vehicle of infection and microbiological surveys may be needed to discover the extent, frequency, and mode of transmission so that long-term control measures can be designed and implemented. For example, the discovery that bulk egg products were a vehicle of infection of paratyphoid B and other salmonella infections led to extensive studies of the bacteriology of these products and to improved hygienic methods of production and pasteurization. The identification of Legionnaires' disease and its association with cooling towers of air-conditioning systems and with piped water systems in large buildings led to studies of the growth of legionellae in these systems and subsequently to improvements in design and maintenance to prevent colonization and growth of the organism.

MATHEMATICAL MODELS OF INFECTIOUS DISEASE

The idea of modelling epidemic diseases dates back to a seminal paper published at the beginning of the twentieth century by Hamer (1906), which suggested that cycles of measles infections and deaths were not due to changes in the pathogenicity of the measles virus, but to changes in the number of susceptible and immune individuals over time. Mathematical models have grown in sophistication over the last few decades particularly with increases in computing power; however, all are based on the logical deductions proposed by Hamer. Infectious disease models are used not only to predict epidemics of disease, but also to help understand disease transmission patterns, to measure the burden of infection, and to anticipate the impact of infection control measures and immunization policies.

The potential for an infectious disease to spread from person to person is known as the basic reproductive rate (R_0). It represents the average number of secondary infections produced in a totally susceptible population by a single case during the entire infectious period. The value of R_0 depends on:

- the probability, for a given disease, that an infected person will transmit infection to a susceptible person
- the frequency of contacts with susceptible persons
- the period of time for which an infected person is infectious.

The value of R_0 is normally signified by the equation:

$$R_0 = \beta \times \kappa \times D$$

where β is the risk of transmission per contact, κ is the number of contacts, and D is the duration of infectivity of the case.

When a new disease enters a virgin population, if $R_0 > 1$ there will be an epidemic, if $R_0 = 1$ the disease will become endemic, and if $R_0 < 1$ the disease will eventually disappear. Childhood diseases generally have a high R_0 and confer lifelong immunity, since nearly everyone is exposed to them early in life, but subsequently protected from disease. For example, classic studies by Hope Simpson (1952) on the spread of childhood infectious diseases among household contacts in a rural area of England derived values for attack rates (β) of 0.80 for measles, 0.72 for chickenpox, and 0.38 for mumps. A case of measles is thought to be capable of

infecting 15 other people on average in a susceptible western population, and so has an $R_0 = 15$.

In practice, populations are seldom totally susceptible. Furthermore, if the disease is one that gives rise to immunity and no more susceptible people enter the population, then the number of susceptible people will decline with time and more and more of a person's contacts will be with people who are immune. The chance of spreading the disease gradually becomes less and less, and the actual reproductive rate (R) of the infection decreases (although the basic reproductive rate (R_0) remains the same) until the epidemic eventually dies out.

The steps that are involved in developing and using a model for an infectious disease have been described in detail (Habbema et al. 1996). They are illustrated in Figure 7.

The kind of model structure chosen will depend on the various transition states of the infection, for example, between the categories susceptible, infectious, and immune. A simple model could be represented as follows:

Susceptible → Infected → Infectious → Immune

This model would be appropriate for a disease such as measles. Estimates are required for the transition intervals between each category in order to begin to develop the model. If the model is intended to describe the long-term dynamics of an infection then other parameters such as births, migration patterns, and deaths may need to be incorporated. The model population may also need to be split into subgroups if, for example, the dynamics of infection in different age groups are to be studied.

The next step is to choose the model type, usually either a deterministic or stochastic model. Deterministic or compartmental models aim to describe broadly what happens in the population as a whole. They tend to categorize individuals into subgroups or compartments and describe the transition between categories using average transition rates. They require fewer data and are relatively easy to set up. For example, an age-structured deterministic model showed that routine varicella immunization of preschool children would probably result in a substantial reduction in uncomplicated chickenpox and in cases requiring hospitalization, but that the number and age distribution of cases would depend strongly on the characteristics of the vaccine (Halloran et al. 1994). Stochastic models (or Monte-Carlo simulation models) often try to describe the effect of disease on every individual in the population. They do this by incorporating chance variation into the disease transmission process in order to model a range of possible outcomes. Compared to deterministic models they are more intuitive, they can follow disease dynamics in all individuals in the population, and they can provide estimates of the range within which an outcome may lie, taking account of chance variation. They are, however, laborious to set up and

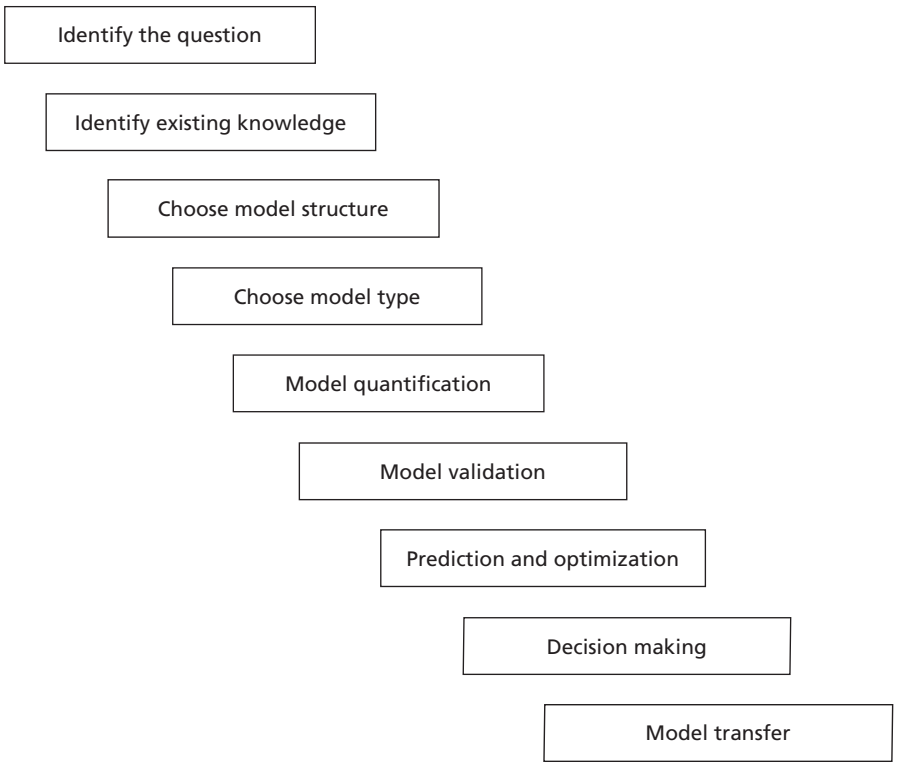

Figure 7 *Steps in developing and using a model for an infectious disease*

many simulations need to be run in order to obtain useful predictions. For example, this approach has been used to model the epidemic of hepatitis C in France based on the temporal pattern of deaths from hepatocellular cancer (Griffiths and Nix 2002).

Once the form of the model has been determined, the rates and distribution of flows between disease transition states need to be quantified. This stage is often problematic because of the lack of reliable data. Key data requirements include the probability that a specific infectious and susceptible individual comes into sufficient contact to transmit infection during a given time period (β), the risk of a specific individual becoming infected per unit time (related to the incidence rate in person years or force of infection), becoming infectious per unit time, and becoming immune per unit time. Sometimes primary data collection is required to make up for deficiencies in the data available. Models then need to be validated by checking outputs against known data, and optimized by testing various model assumptions in a process of sensitivity analysis, before the results of the model can be applied to decision-making and public health practice.

Historical perspective	2	Zoonoses and emerging infections	21
Basic principles	4	References	21
Environmental and social effects and population immunity	19		

INTRODUCTION

Successful control of an infectious disease requires an understanding of the characteristics and behavior of the agent causing disease and its interaction with the hosts it infects and with the environment. This may seem an obvious statement, however history is littered with failed attempts at controlling infectious diseases through ignorance of basic issues such as the mode of transmission, natural reservoirs of infection, and the role of carriers (Table 1).

For example, in the early nineteenth century cholera was thought to be an airborne disease. Control efforts at that time were based on remedies to ward off contaminated atmosphere ('miasma'). It was not until 1854 that John Snow, a British epidemiologist, showed that cholera was a water-borne infection. Snow's discovery was based on the simple observation, during a cholera epidemic, that attack rates were highest in people who obtained their drinking water from one particular pump (Figure 1). His remedy – to remove the handle of the pump and thereby stop the outbreak – revolutionized the control of cholera and presaged a series of public health measures aimed at improving the safety of drinking water. Unfortunately, ignorance about cholera control persists to this day. When the seventh cholera pandemic reached Latin America in 1991, the reaction of many countries was to introduce a requirement for all visitors to be vaccinated. Cholera vaccine may provide some individual protection against disease, but does not prevent cases from excreting *Vibrio cholerae*. As a public health measure it therefore has no value in controlling the spread of infection (Finkelstein 1984).

A particular area of medicine in which knowledge of disease transmission and so how control can be effected, is immunization. There are several characteristics of an infection that determine how readily it may be controlled by vaccines. These characteristics include the infectivity of the disease, the length of the incubation period, the duration of naturally acquired and vaccine-induced immunity, and the presence or absence of subclinical infection and nonhuman hosts (Noah 1988). An especially important concept for immunization is herd immunity, the proportion of a population or group that are immune to a specific infection (Topley and Wilson 1923; Anderson and May 1985b; Last 2001). Mathematical models that incorporate these effects can be used to predict the outcome of alternative vaccine strategies, under varying assumptions about vaccine efficacy and vaccine coverage. This type of information has been pivotal in the design of successful immunization programs against diseases such as smallpox, poliomyelitis, and measles, and predicting the effectiveness or otherwise of proposed interventions.

In this chapter we will describe the basic theory of infectious disease transmission, and consider how the application of theory contributes to the control of communicable disease in man.

Table 1 *Factors affecting transmission and determining means of infectious disease control*

Factors affecting transmission	
Reservoirs of infection	Human
	Animal (Zoonoses)
	Environmental
Modes of transmission	Respiratory – droplets, aerosols
	Oral–gastrointestinal
	Parenteral
	Fomites
	Sexual
	Vectors
	Vertical (mother-to-child)
Period and duration of infectivity	
Subclinical infectious carriers	
Level of infectiousness (R_0 and R)	
Behavior and contact patterns of those infected	
High risk situations and core groups	
Effectiveness of treatments in reducing infectiousness	
Resulting immunity following infection or immunization	
Genetic susceptibility	

HISTORICAL PERSPECTIVE

The theory of infectious disease transmission has its origins in the first decade of the twentieth century. Following the discovery of germ theory in the nineteenth century, scientists tried to understand the cycles in the incidence of many infectious diseases. In particular, they sought an explanation for the regularly recurring epidemics of diseases, such as measles, and why these epidemics peaked and died out before all susceptible persons had been infected. In 1906, William Hamer proposed a model in which he considered the cases to occur in discrete, 2-week generations. The number of cases of disease in one generation was assumed to be a constant multiple of the number of cases in the previous generation and the number of susceptibles. On this simple assumption, Hamer was able to explain the epidemic nature of measles: the regular cycles were caused by the depletion of the number of susceptibles during an epidemic followed by a gradual reaccumulation as more children were born. His argument, however, was not widely accepted at the time. An alternative, empirically derived theory, due to Brownlee (1907, 1909), was based on Farr's (1840) observations of the shape of epidemic curves. According to this theory, the infectivity of the agent was reduced by a constant factor with each successive generation of cases in the course of an epidemic: the decay of an epidemic was due to this attenuation of the infective agent and not to a

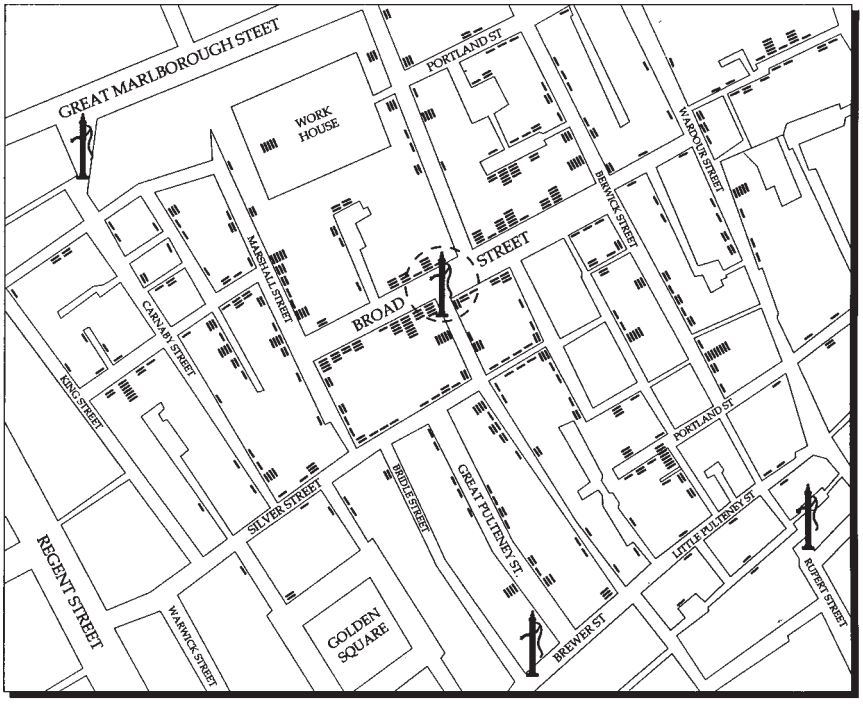

Figure 1 *Distribution of cholera deaths, Golden Square, 1854*

lack of susceptible persons. (An account of Brownlee's work is given by Fine (1979).) Contemporary with this debate, Ross (1909, 1911) proposed a model of malaria transmission along similar lines to Hamer's theory of measles. Both Ross and Hamer were well aware that their models were a great simplification of the heterogeneity of real populations, but realized that they captured the fundamental mechanisms underlying the observed patterns of disease incidence.

It was against this background that Topley and Wilson commenced their classic series of experimental studies of the spread of infection among mice. The carefully controlled conditions in the mouse populations were ideal for testing the competing theories. At the outset of this research Topley (1919a, b, c) set out the main problems to be investigated in his Goulstonian Lectures to the Royal College of Physicians of London. It is clear that he was influenced by Brownlee's ideas, but did not dismiss Hamer's theory: 'Though reasons have been given for believing that the outstanding feature in the subsidence of an epidemic is a loss of infectivity by the bacterial virus [sic], yet the resistance of the host cannot be a negligible factor. It will operate by decreasing the concentration of susceptible individuals, and hence the chances of successful transference.' After 5 years of experiments, Topley and Wilson (1923) were led to the conclusion that 'the question of immunity as an attribute of a herd should be studied as a separate problem, closely related to, but in many ways distinct from, the problem of the immunity of an individual host'. Theirs was the first published reference of the term 'herd immunity'. Its use indicates that the focus of the research was moving away from the properties of the infective agent alone and towards also considering properties of the herd or population. Their most seminal finding was that the addition of a number of susceptible mice to a population in which a bacterial parasite was at equilibrium produced an outbreak of disease (Topley 1923). Similar observations in a human population, on the incidence of diphtheria in a boarding school, were made by Dudley (1926): outbreaks recurred when the admission of sufficient susceptible new boys had removed the herd immunity. Two decades later experiments by Webster (1946) in the United States confirmed this. Gradually, Hamer's theory became accepted as the experimental evidence mounted, while no evidence to support Brownlee's theory of varying infectivity was obtained. A full account of the series of mouse experiments in Britain is given in the final Medical Research Council report (Greenwood et al. 1936).

During this period there was further theoretical progress. Kermack and McKendrick (1927) proved the existence of an epidemic threshold, i.e. that an epidemic would occur if, and only if, the proportion susceptible exceeded a given level. Soper (1929) provided a clear statement of Hamer's model and its continuous time equivalent. He showed that the continuous model produced damped oscillations around the equilibrium solution and derived the period of small oscillations. He also noted the similarity with some laws for chemical reactions, hence the model is sometimes referred to as being of 'mass action'. The inability of this model to yield the undamped epidemic cycles observed for measles was seen as a major flaw, until Bartlett (1956) demonstrated that a stochastic formulation of the Hamer–Soper model overcame this problem. His numerical simulations generated recurrent epidemics with no tendency to the equilibrium. He noted that the size of the population influenced the pattern of epidemics: larger towns had more regular cycles, whereas 'fade out' of infection often occurred in simulations with a small population. This led him to derive a critical community size above which fade out was unlikely (Bartlett 1957), a result which accorded well with observations. Bailey provided the first comprehensive account of 'The mathematical theory of epidemics' in which these developments were discussed (Bailey 1957). The text also included methods for estimating parameters (such as latent and infectious periods) from epidemiological data.

Meanwhile, in the United States, Reed and Frost were developing a model which has become the basis for the study of outbreaks in small populations. This included a nonlinear term to discount the effect of two or more infectious individuals contacting the same susceptible person (Frost 1976). Fox et al. (1971) explored the effects of superimposing family and other structures on a Reed–Frost model, the first study to include heterogeneity in contacts between members of a population. Their stochastic simulations led them to emphasize the important role that small pockets of susceptible individuals could play in sustaining transmission.

The concept of the basic reproduction number (R_0) was introduced to infectious disease epidemiology by Macdonald (1957) in the context of his studies of malaria. R_0 has become a central feature of the theory of infectious diseases since Dietz (1975) and Hethcote (1983) first used it in the study of directly transmitted infections. It provides a simple method of comparing diseases and the difficulty of eliminating them. Dietz (1975) showed how, in a simple homogeneous model, R_0 could be estimated from the average age at infection. Diekmann et al. (1990) provided a rigorous mathematical framework for the definition of R_0 in models of disease transmission in heterogeneous populations. These include the models with age-dependent transmission rates developed by Anderson and May (1984, 1985a, b) and others (Schenzle 1984; Hethcote 1983) that have been used to investigate the dynamics of a wide range of infections and to explore the effects of different vaccination programs (Anderson and Grenfell 1986; Babad et al. 1995; Anderson and May 1985a, 1990; Anderson et al. 1987; Halloran et al. 1994). These considerations are now applied to many other infections apart from those for which effective vaccines are

available and have become increasingly influential on policy decisions relating to control of infectious disease, including when traditional control measures are applied to new infections such as severe acute respiratory syndrome (SARS) and avian influenza (WHO 2003; Anderson et al. 2004). Mollison et al. (1994) has reviewed developments across the entire spectrum of modeling approaches and highlighted areas in which further research is needed. Particular developments took place in the 1980s and 1990s when attention was focused on the epidemiology of human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS). Models for sexually transmitted diseases and other sexually transmitted infections (STI) often require many population subgroups with widely differing activity levels and the long incubation period for AIDS and its changes in infectivity present further complications (Johnson et al. 1992; Boily et al. 2000; Aral 2000). Most recently, field observations were combined with modeling approaches in real time to rapidly determine how best to control severe acute respiratory syndrome (SARS) (WHO 2003).

BASIC PRINCIPLES

Infection in the individual

There are several stages in an episode of infectious disease (Figure 2). The process begins when a susceptible individual is exposed to an infectious case. If transmission of the infectious organism occurs, and the organism begins to multiply in the tissues of the exposed individual, then the individual can be considered to have been infected. Not all exposures result in transmission, and of these only a proportion progress to clinical disease. At this early stage the individual is not yet infectious – this is known as the latent period of infection.

The next stage is when the infected individual begins to shed the organism from the respiratory or gastrointestinal tract or in body fluids, such as blood or urine. At this point the individual is infectious, i.e. capable of transmitting the organism to others. The period of latency has now ended. This next stage marks the beginning of the period of infectivity.

Throughout both the latent period and the early stages of the period of infectivity, the individual has no symptoms. The onset of the first symptom heralds the end of the incubation period, which is defined as the interval between the initial exposure and the onset of symptoms. For some infections, symptoms appear at the same time as the patient becomes infectious. For others, infectiousness rises as symptoms worsen, while for a third group it is more usual for infectivity to precede symptoms by a few days. It is unusual for infectivity to be constant through the infectious period.

The next stage is reached when the individual is no longer infectious. Normally this occurs while symptoms are present. In many infections the organisms are cleared from the body and immunity develops. In some diseases, shedding of the organism can continue after symptoms have resolved. This tends to occur particularly in immunosuppressed individuals. When shedding of the organism becomes persistent, then the individual has become a carrier. Knowledge of carrier states is particularly important in understanding the dynamics of disease transmission. Some patients may be asymptomatic carriers for years, for example as occurs in typhoid fever, while for some persistent viral infections such as hepatitis B and C and HIV, individuals may remain infectious, but without symptoms for many years (Heyman 2004; Aral 2000).

In some infections the symptoms resolve and the patient is no longer infectious, but the organism remains dormant, i.e. the infection re-enters the latent period. The disease may then subsequently reactivate, some-

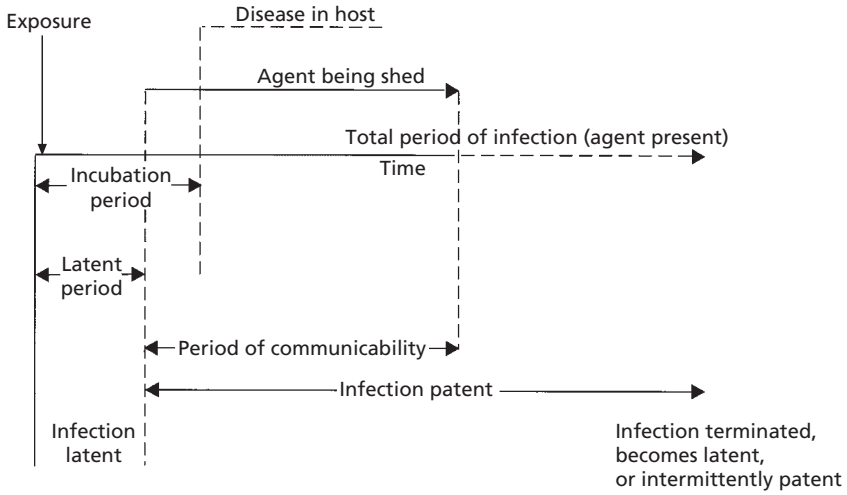

Figure 2 *Stages of infection*

times years later, with shedding of the organism. Varicella and malaria are examples of infections that commonly become latent. In other chronic infections, such as HIV, there may be an initial illness followed by a prolonged latent period with a more serious later illness years later (see Human immunodeficiency virus, in the *Virology* volume in this series). For hepatitis B the infection is commonly cleared, but in some cases the infection and infectiousness becomes chronic perhaps leading to severe disease later (Hepatitis B, in the *Virology* volume in this series).

The duration of the latent and infectious periods are important parameters of mathematical models. Classic epidemiological studies which observed the interval between primary and secondary cases within households enabled these parameters to be estimated for measles and other infections (Hope Simpson 1948; Bailey 1956a, b).

DEVELOPMENT OF IMMUNITY

The immunological basis for the development of immunity to bacterial infections is considered in the *Immunology* volume in this series. From the perspective of infectious disease transmission theory and control, there are a number of key components to be considered.

Some infections do not result in significant natural immunity and consequently can be acquired repeatedly. Gonorrhea and chlamydia are examples (Aral et al. 1999; Stoner et al. 2000). For infections that do stimulate an immune response, the duration of immunity influences the rate at which susceptibles accumulate in a population. Generally speaking, naturally acquired immunity is longer lasting than vaccine-induced immunity and in some infections immunity may be lifelong.

It is particularly important to distinguish between immunity against infection and immunity against disease. For example, live oral polio vaccine protects against both infection and disease, whereas inactivated polio vaccine protects predominantly against disease. This difference has significant implications for control programs – control of a polio epidemic can be achieved much more rapidly, and with lower vaccine coverage, with live vaccine than with inactivated vaccine.

Cross-immunity may occur with one prior infection giving some immunity to another different infection. Breastfeeding reduces susceptibility to a number of infections that affect infants and young children. The influence of maternal antibody which has crossed the placenta in utero is a highly significant factor in infections where transmission is common among babies. For example, the incidence of meningococcal disease in infants bears an inverse relationship to the decline in maternal antibody (Figure 3). The peak incidence is at 6 months of age, coinciding with the nadir in maternal antibody. After 6 months, naturally acquired immunity begins to develop and the disease incidence declines. The significance for control measures is that any vaccine for use in a mass immunization program would need to be effective during the window of susceptibility in early life.

Infection in the population

The course of infection in the individual has a strong influence on the pattern of disease in a population. Diseases that confer permanent immunity after a short infection, such as measles and rubella, occur naturally in a cycle of regularly recurring epidemics. Diseases for which individuals become susceptible to reinfection on recovery (e.g. gonorrhea), or some infected individuals become long-term carriers (e.g. hepatitis B, tuberculosis), do not show such a regular pattern (Noah et al. 1995).

Factors specific to each population, including demographics, behavioral patterns, and environmental factors also affect the incidence of the disease. These determine whether, and at what level, an infection can remain endemic in a particular population. There are many infections that have a widely differing level of endemic infection in industrialized and resource-poor countries. Hepatitis B is commonly acquired in childhood in

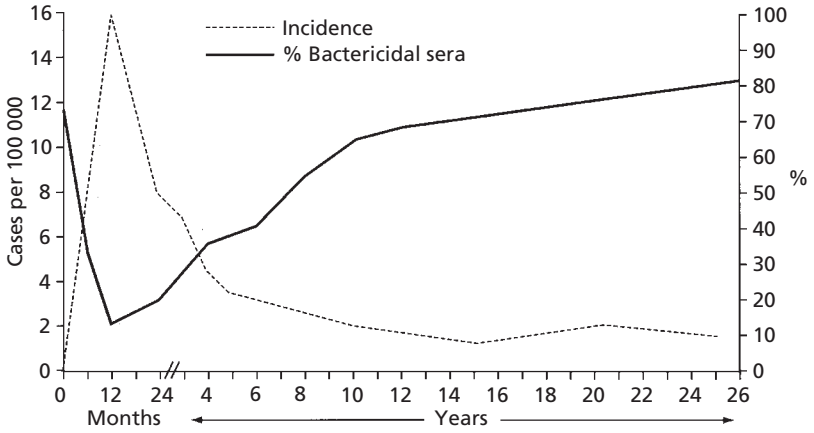

Figure 3 *Relationship between age-specific incidence of meningococcal infection and immunity (after Goldschneider et al. 1969).*

sub-Saharan Africa, but is largely confined to adults in particular risk groups in Northern Europe. Hepatitis A, and other infections transmitted by the fecal–oral route, are acquired at a younger age in countries where sanitation is poor (see Control of disease by hygiene). The zoonoses mostly occur where their specific animal hosts are to be found and humans are exposed, Legionnaires' disease is almost unheard of where its environmental reservoir of piped water is not found (Giesecke 2002). The differences are less striking for infections such as measles and rubella, but these too are acquired at a younger age in less developed countries. The contrasting epidemiology of an infection in different populations may necessitate entirely different approaches to disease control.

BASIC REPRODUCTION NUMBER

The basic reproduction number (R_0) for an infection within a population summarizes the effect of many of these factors in a single parameter. (It is variously termed the basic reproductive/reproduction rate/ratio/number by different authors, but almost always denoted R_0; and pronounced R nought, R zero or R subzero!) It is defined as the number of secondary infections that a typical infectious individual would produce in a completely susceptible population (Anderson and May 1991; Dietz 1993). Thus, R_0 depends both on the properties of the infective organism and on the social and demographic characteristics of the population. It may vary between infections, but also for the same infection in different populations. R_0 can be interpreted as the average number of contacts made by an individual during the infectious period; a contact being defined as any encounter in which an infectious individual would transmit infection to a susceptible individual (a definition that is clearly disease specific). This is a crucial variable for designing rational control programs. Some accepted values of R_0 for different common infections are shown in Table 2. Infections with high values of R_0 are regarded as highly infectious. Vaccine preventable diseases with a high R_0 are much more difficult to eliminate than those with low R_0. For example, a human infectious disease with an $R_0 = 20$ and without an environmental reservoir requires a population immunity of 95 percent or higher to achieve elimination, whereas one with $R_0 = 4$ requires a population level immunity of only around 75 percent.

Where infections have relatively low values for R_0 and are not infectious during the latent period, control may be effected by case finding and isolating those affected or influencing them to reduce infection risk (for example by condom use for sexually transmitted infection). This will be less successful or impossible if R_0 is high and transmission can take place before symptoms appear or immunity emerges. For example compare SARS, sexual acquisition of HIV, influenza, and measles (Table 2).

EFFECTIVE REPRODUCTION NUMBER

In most real situations, not all of the population are susceptible to infection: some are immune either as a result of previous infection or through vaccination. Some of the contacts of an infectious person will not result in new infections but be 'wasted' on immune individuals. The effective reproduction number R is defined as the number of secondary cases produced by a typical infectious individual (Anderson and May 1991). Clearly R depends on R_0 and the susceptibility of the population. For a simple homogeneous model (in which contact between any two individuals is assumed to be equally likely) $R = R_0x$, where x denotes the proportion of the population who are susceptible.

Persistence thresholds

An infection can only establish itself in a population if $R_0 > 1$. Any such infection has an endemic equilibrium state at which $R = 1$, i.e. where a typical infectious individual produces on average one secondary infection. At this equilibrium state only one of the R_0 contacts made by an infective is with a susceptible individual. In the simple model, the proportion of the population who are susceptible is $1/R_0$. The equilibrium at $R = 1$ is a threshold: if $R > 1$ the number of infections increases; if $R < 1$ the number of infections decreases. Many infections demonstrate this threshold behavior in their natural epidemic cycles. During these cycles R oscillates around 1 as the proportion susceptible oscillates around the equilibrium value.

The $R = 1$ threshold is the key to designing vaccination and other control programs. If a vaccination program aims to eliminate a disease in a population, it must maintain $R < 1$, so that the number of infections decreases with each successive generation of cases. The necessary level of immunity could be achieved, in the long term, by immunizing a proportion p of the population at birth,

Table 2 *Selected infections – what stage infection can take place at and some estimated values for* R_0

Infection	At what stage infection generally takes place	Basic reproduction No. R_0
HIV (sexual transmission)	At any stage	<1 (per single sexual act)
Influenza	Prior to or during symptoms	3–4
Measles	Prior to or during symptoms	Around 10
Severe acute respiratory syndrome	Not prior to symptoms, infectiousness peaks in second week	2–3

where $p = 1 - 1/R_0$ (so that only a proportion $1 - p = 1/R_0$ of newborns remain susceptible).

HERD IMMUNITY

The above arguments suggest that it is possible to eliminate a vaccine preventable infection without immunizing every member of the population. It is this concept of indirect protection of susceptible individuals to which the term 'herd immunity' has been attached, although many authors have been deliberately vague in any definition. Fox et al. (1971) discussed a dictionary definition of herd immunity as 'the resistance of a group to attack by a disease to which a large proportion of the members are immune, thus lessening the likelihood of a patient with a disease coming into contact with a susceptible individual'. In a wide-ranging review, Fine (1993) points out the ambiguity of this definition – it fails to distinguish between total protection (when the immunity of the herd is above the threshold and the disease cannot persist) and partial protection (where the presence of some immune individuals lessens the risk to a susceptible). The threshold concept is the more appealing, and it leads to a definition of a population having herd immunity if $R < 1$. An equivalent statement of this definition is 'a population is said to have herd immunity to an infection if a typical primary infection produces less than one secondary infection'. Such a concise definition has the advantage of clarifying a sometimes vague concept; either a population has herd immunity, or it does not. The amount by which the population is above or below the herd immunity threshold is quantified by the effective reproduction number R.

Although the concept of herd immunity has been defined, there is still a need to clarify what is meant by a 'typical' infective. In a simple homogeneous model all individuals in the population are assumed to have the same number of contacts. Every infective is typical. In more complex models, which incorporate heterogeneity in the contact process, the typical infective is defined as some suitably weighted average of all infectives. (The typical infective is determined through a defined mathematical framework as the fastest growing stable distribution of infectives (Diekmann et al. 1990.) The definition of a population having herd immunity if $R < 1$ is applicable to these more complex models. The factors determining the effective reproduction number are the number of contacts made by infectives and the levels of susceptibility. The immunity of the herd does not depend necessarily on the immunity of individuals. For example, a population in which an infection has an $R_0 < 1$ has herd immunity to that infection even if no individuals are immune.

ESTIMATION OF R_0

Dietz (1993) has reviewed the variety of methods that have been used to estimate the basic reproduction number for infectious diseases. Many require data on the endemic state of the disease before the introduction of any control measures. Perhaps the most simple of these is (Anderson and May 1991):

$$R_0 = \frac{N}{B(A - m)},$$

where N is the population size, B is the annual number of births, A the average age at infection and m is theaverage duration of protection from infection provided by maternally derived antibodies. For stable populations this expression reduces to $R_0 = L/(A - m)$, where L denotes the life expectancy. (A brief heuristicjustification of this formula is possible for populations where virtually all individuals are infected during their lifetime: $A - m$ is the average duration of susceptibility so the proportion susceptible $Rx = (A - m)/L$, and at equilibrium $R_0 = 1/x$.) In deriving these simple formulae it is assumed that the risk of infection for a susceptible individual (often called the force of infection) is independent of age. The complications introduced by an age-dependent force of infection, which preclude the derivation of an explicit formula for R_0, are discussed later.

Mathematical modeling

The essential requirement of a mathematical model isthat it describes the mechanism underlying the processof interest. The key to models of infectious diseases is an understanding of the interactions between infectious and susceptible individuals that result in the transmission of infection. These should be described by a set of clearly stated assumptions, which can then be expressed as mathematical equations relating the variables and parameters of the model. The model is simply the means of evaluating the consequences of a set of assumptions.

When formulating a model, a compromise must be reached between simplicity and overcomplication. Simple models, which may have explicit solutions, clearly demonstrate the effect of each parameter, but may grossly oversimplify the complexities of the transmission process. More complicated models provide greater flexibility, but each additional refinement introduces more parameters thereby increasing the task of parameter estimation and making it more difficult to discern the effect of any individual parameter. In general, simple models are most useful for investigating qualitative effects, whereas more detailed models are needed for quantitative predictions.

When interpreting the results of any modeling exercise, it is essential to bear in mind the assumptions on which the model is based. No model can fully describe all the complexities of the transmission of a disease in a population. However, models can greatly enhance the understanding of the processes underlying disease

transmission, and play an important role in the rapid design of control programs, for example, during the control of SARS, modeling, along with observational techniques, was used to quickly estimate the disease's R_0 and this, with other parameters, was used to inform the control strategy (WHO 2003; Anderson et al. 2004).

The examples in this part of the chapter will concentrate on infections for which humans are the only host, that have short latent and infectious periods and confer permanent immunity, as exemplified by measles. A flow diagram illustrates the basic structure of a model for such an infection showing the compartments that may be included (Figure 4). Models for other infections, such as those that confer no immunity or which have a carrier state, require this structure to be adapted accordingly. Anderson and May (1991) present and discuss models with different structures, which are used for a wider range of infectious diseases such as zoonoses, sexually transmitted infections, and infections with environmental reservoirs for which modeling approaches are also used (Anderson and May 1991). Some of these will be considered later in this chapter.

DYNAMIC BEHAVIOR

Numerical simulations of infectious disease transmission proceed in discrete timesteps to describe the changes over time in the number of individuals in each of the model's compartments. The values at each timestep are calculated from the values at the previous timestep, starting from some specified initial values. This procedure is essentially the same for all models, although complex models may have more compartments or further stratification by age, sex, etc.

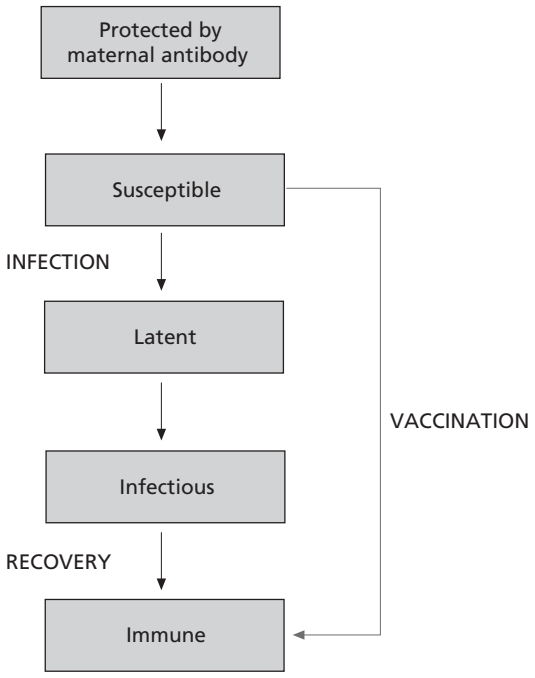

Figure 4 *Flow chart showing the compartmental structure of mathematical models*

The rates at which transitions between compartments occur are determined by the model's assumptions and parameters. For example, the rate at which individuals move from the latent to the infectious compartment is governed by the latent period, and the rate of movement from infectious to immune by the infectious period. The crux of all models of disease transmission is the rate at which susceptibles are infected, referred to as the force of infection, and how this is assumed to depend on the number of infectious individuals.

The mass action assumption

The force of infection, λ, is the rate at which susceptible persons acquire infection. The probability that a given susceptible individual will acquire infection in a short period δt is $\lambda \delta t$. For a directly transmitted infection, the force of infection at any time depends on the infectives present in the population at that time. The simplest assumption is that the force of infection is directly proportional to the total number of infectives. The rate at which new infections occur in the population is then proportional to the product of the number of susceptibles and the number of infectives. This model is known as the mass action model because of its similarity with the model for chemical reactions.

Hamer's discrete time model

The simplest version of a mass action model is that originally used by Hamer (1906) to describe measles epidemics in London. He considered infections as occurring in discrete generations, denoting the number of susceptibles and infectives in the nth generation by S_n and I_n, respectively. The number of susceptibles and cases in the following generation were calculated from the difference equations

$$I_{n+1} = \tfrac{1}{m}\, I_n \mathit{ThickSpace} S_n$$
$$S_{n+1} = S_n - I_{n+1} + \mathit{ThickSpace} b.$$

Thus the number of new infections is assumed to be proportional to the number of susceptibles and the number of infections (the 'mass action' assumption); all infections from the previous generation are removed (by recovery or death). The number of susceptibles is decreased by the number of new infections and increased by the influx of b susceptibles at each timestep; it is assumed that there is no mortality of susceptibles.

The only parameters of the model are the time between generations, the number of susceptibles added at each timestep, and the critical number of susceptibles, m. (The critical number of susceptibles m can be written in terms of the basic reproduction number R_0 and the population size N as $m = N/R_0$. The mass action assump-

tion then has the interpretation that each of the I_n cases makes R_0 contacts, of whom a proportion S_n/N are susceptible; leading to $I_{n+1} = R_0\, I_n\, S_n/N$ cases in the next generation.) Hamer used a 2-week generation time (the sum of the latent and infectious periods for measles), and the values $b = 4\,400$ (there were approximately 2 500 births per week, but 300 of these babies died before losing protection from maternal antibodies at 6 months of age) and $m = 150\,000$ (determined empirically).

The model produces a series of undamped regularly recurring epidemics, whose magnitude and period depend on the parameters and initial conditions. Hamer used initial values of $I_0 = 12\,800$, $S_0 = 150\,000$ to produce a cycle with a period of 18 months (i.e. 39 2-week periods) (Figure 5). He noted that the number of susceptibles was fairly stable during the course of an epidemic cycle, oscillating by just 20 percent around the equilibrium number of 150 000. If the number of susceptibles exceeds this threshold there are more infections in the next generation, i.e. $I_{n+1} > I_n$ if $S_n > m$; if the number of susceptibles is below the threshold, the number of infections decreases. (The effective reproduction number at the nth generation, $R_n = S_n/m$, and oscillates around 1 during the epidemic cycle.)

Continuous time model

The continuous time equivalent of Hamer's model produces damped epidemic cycles (Soper 1929). The period of these cycles, T, can be calculated analytically (Soper 1929) and expressed in terms of the average age at infection, A, and the combined length of the latent and infectious periods D;

$$T = 2\pi\sqrt{AD}.$$

Predictions of the interepidemic period using this formula correspond well with observed values for many infections (Anderson and May 1991).

Reed–Frost model

The Reed–Frost model is preferred to the mass action model for outbreaks in small populations. Again, cases are considered as occurring in discrete generations, and let p be the probability of contact between any two individuals in each timestep. The probability of a susceptible being infected is modeled as the probability of meeting at least one infective, which is $1 - (1 - p)^{I_n}$. In this formulation the number of new infectives is not proportional to the number of infectives in the previous generation, as the model accounts for the possibility that a susceptible may be contacted by more than one infectious individual.

HETEROGENEITY

The models considered so far have been homogeneous models in which all susceptibles in the population experience the same force of infection. This is undoubtedly a gross simplification of most real situations. For infections such as measles, mumps, and rubella, the force of infection is highly age dependent due to heterogeneity in contact patterns (Farrington 1990; Grenfell and Anderson 1985; Anderson and May 1985a); in schools, children have most contact with other children of the same age. Changes in transmission rates as schools open and close can account for the seasonality of measles (Fine and Clarkson 1982a; Schenzle 1984). For sexually transmitted diseases, the degree of mixing between different subgroups of the population may be crucial in determining the spread of infection (Aral 1999; Aral et al. 1999; Gregson et al. 2002). For other infections, spatial factors such as population density may play a role, or genetic differences in susceptibility may exist (Anderson and May 1984). Control of infections spread by intimate contact, notably sexually transmitted infections, have to take into account factors such as sexual networks, partnership patterns, and diverse behaviors with varying risk of infection. Heterogeneity in the

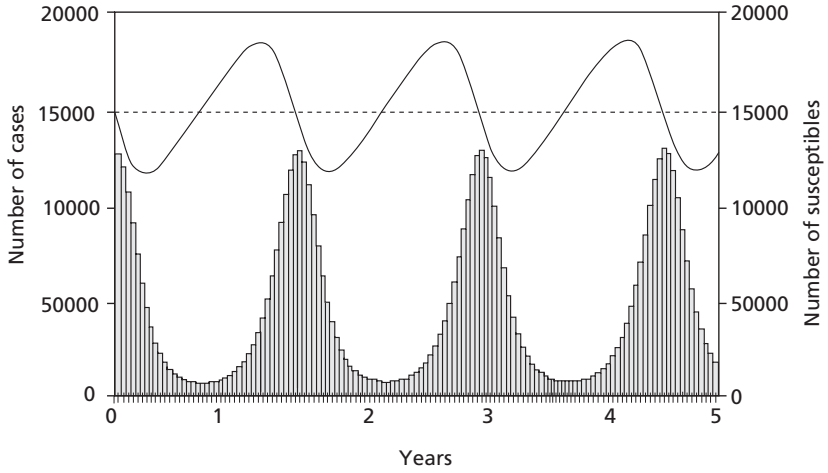

Figure 5 *Number of cases and susceptible individuals predicted by Hamer's discrete time model for measles in London.*

application of control measures such as vaccination may introduce further problems, e.g. pockets of susceptibility from unvaccinated communities or clustering of vaccination failures. The simple homogeneous model can be generalized in order to investigate these effects (Anderson and May 1991).

DETERMINISTIC AND STOCHASTIC MODELS

The transmission of an infection between individuals in a population depends on a number of chance events. In a large population, with many such events, the observed behavior will be close to that expected from averaging random effects. Deterministic models examine the expected behavior of a system; running a deterministic simulation under the same conditions gives the same result every time. This makes them easy to work with.

The major weakness of deterministic models is their behavior in a situation with a small number of susceptibles or infectives, where individual random events may influence the outcome. This may arise from an outbreak in a small population such as a school, or from a very low level of infection in a large population, perhaps as the result of a successful vaccination program. An example of infection outside vaccine preventable diseases is SARS where a small proportion of cases results in superspreading events (WHO 2003; Anon 2003). Stochastic models, which use randomly generated numbers to determine the outcomes of individual events, are better suited to such situations. Stochastic simulations are usually repeated many times to generate a range of results, so that the probability of an outbreak of a particular size or duration can be inferred.

The difference between deterministic and stochastic formulations is illustrated by the case of introducing a single infective into a population in which there is no infection. If $R > 1$, a deterministic model will always generate the same outbreak, whereas with a stochastic model one possibility is that no secondary transmission occurs (this may even be the most likely outcome). Alternatively, if $R < 1$ no significant spread occurs in a deterministic model, whereas a stochastic model has a finite probability of generating a large outbreak.

A combination of stochastic and deterministic approaches may be required at different stages of the same problem. The investigation of the effects of introducing a mass vaccination program in a population is an appropriate application for a deterministic model. If the program was implemented successfully to eliminate endemic infection, stochastic modeling could be used to yield the distribution of the size of outbreaks expected from any infections that come into the population, for example from abroad.

Strategies for disease control

The strategy adopted to control an infectious disease will depend on many factors including the aim of the program, the availability of resources, the acceptability of possible measures, and all the factors around the epidemiology of the disease (Table 1). This section outlines the possible aims, describes the strategies available, and discusses when they are appropriate.

AIM OF A CONTROL PROGRAM

Programs for disease control need to have clearly defined aims. The program can be designed to meet this aim and its success in achieving the aim can be assessed (Hawker et al. 2001). The three broad aims are containment, elimination, and eradication (Noah 1988) and a variety of control measures may be available (Table 3).

Containment

Containment is the most modest control option. Infection and infection risk remain endemic in the population or with an imported infection its spread is limited, but morbidity from the disease is reduced to an 'acceptable' level. An example of a containment aim was the WHO measles target for 1995: a 90 percent reduction in measles

Table 3 *Possible control strategies to interrupt or reduce transmission of infection*

Control strategy	Example
Removal of infections from distribution	Contaminated food source
Controlling infection in a nonhuman reservoir	Immunizing chicken flocks against *Salmonella* species
Isolation or cohorting	Isolating infectious patients in hospital – methicillin resistant *Staphylococcus aureus*
Quarantine	Quarantining smallpox contact
Increasing or inducing immunity	Routine immunization
Treatment of those infected	Whooping cough in early stages
Treatment of those potentially exposed	Immunoglobulin given to newborns born to hepatitis B infectious women
Influencing behavior through education and establishing a facultative environment	HIV – condom use by those infected
Reducing transmission in high risk situations	Protective clothing in operating theaters
Preventing spread between populations	Travel restrictions –SARS

cases and a 95 percent reduction in measles deaths from the levels before vaccine was introduced. With many infections, containment is the only possible aim.

Elimination

Elimination of an infectious disease from a population requires that chains of transmission either do not occur or are readily broken. This will mean that there is no endemic transmission of infection within the population, and that an infection imported into the population produces no more than an isolated outbreak. This may be achieved through the herd immunity of the population or by vigorous application of control measures. Either way the effective reproduction number must be maintained below one. Elimination is generally more difficult to achieve where there are reservoirs of infection outside humans, though it may be achieved if inter-human transmission is inefficient, i.e. R_0 is low.

Eradication

Eradication of an infectious disease requires the global destruction of the pathogen that causes it. There has to be no effective environmental or animal reservoir. It eventually allows the cessation of all control measures, potentially providing huge savings for future generations. Smallpox is the only disease to be eradicated so far. The last case of wild smallpox infection occurred in 1977. A WHO program to eradicate polio is in progress. Elimination from the Americas and the Western Pacific has been achieved and significant advances have been made in all other regions, though as of 2004 the infection is stubbornly persisting in six particular countries in sub-Saharan Africa and South Asia (WHO 2004a).

ROUTINE VACCINATION

Routine vaccination is the most common method for administering vaccine to a population. Individuals (usually children) are vaccinated when they reach a target age. Such a program requires maintenance of a suitable infrastructure (to ensure a regular supply of vaccine, have trained staff, informed families, etc.). If the vaccine provides protection against infection (and not just against the disease), the introduction of a vaccination program will affect the circulation of infection.

Age at infection

The dynamic interaction between susceptible and infectious individuals in the population can lead to counter-intuitive results. A vaccination program that leads to reduced circulation of infection, but not elimination, will cause the average age of infection to rise (Figure 6). Unprotected individuals experience a reduced force of infection and so remain susceptible longer, and thus are older when they eventually become infected. The change in the age distribution of cases is even more marked if transmission rates are higher in older age groups. This effect is beneficial if disease is most severe at a young age (e.g. pertussis, measles in developing countries), but it can lead to an increase in morbidity if disease severity increases with age or if it puts fetuses at risk, for example by shifting the age of infection in females into their childbearing years as is the case with rubella (Anderson and Grenfell 1986). Vaccination programs against diseases such as polio and rubella (see later under Rubella: the prevention of congenital rubella syndrome) must achieve high coverage so that the reduction in circulation outweighs the problem of increasing age at infection.

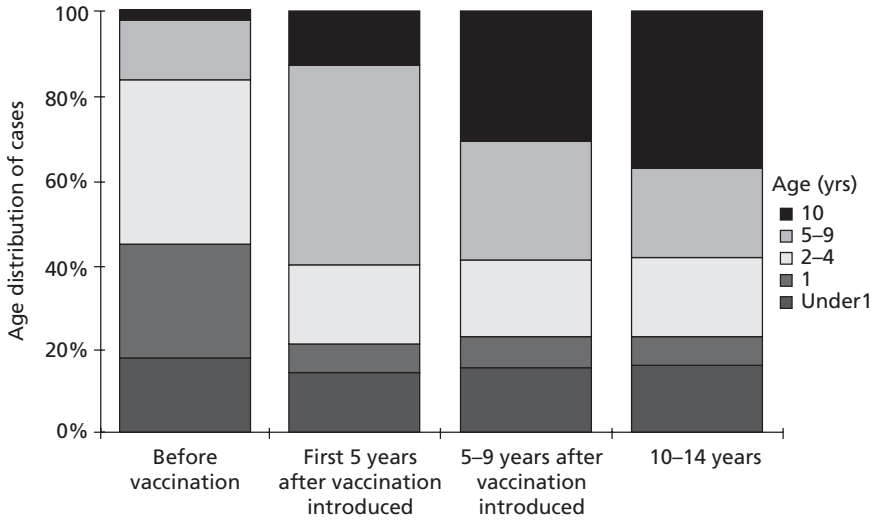

Figure 6 *Modeled change in the age distribution of infection following the introduction of vaccination. Simulation of measles in a developing country before and after the introduction of a routine vaccination program that immunizes 80 percent of children at age 9–12 months. Parameter values: basic reproduction number,* $R_0 = 20$*; life expectancy,* $L = 50$ *years; latent period, 1 week; infection period, 1 week; duration of protection by maternal antibody,* $m = 6$ *months.*

Honeymoon periods

The 'honeymoon period' is the name sometimes given to the period of low incidence that is frequently observed following the introduction of a routine vaccination program, but which (if vaccination coverage or efficacy is not sufficiently high) is inevitably followed by a resurgence of infection (McLean and Anderson 1988; McLean 1995; Chen et al. 1994). When the vaccine is first introduced, many of those above the age of vaccination will be immune through natural infection. Vaccination reduces the proportion susceptible well below the threshold. However, the consequent low force of infection allows unprotected individuals (those who are not vaccinated or in whom vaccination fails to induce immunity) to accumulate. Once the threshold is exceeded, a post-honeymoon epidemic can occur (Figure 7). If the vaccination program is maintained, the infection will settle into a new epidemic cycle with a considerably longer epidemic period than before vaccination.

VACCINATION CAMPAIGNS

Vaccination campaigns aim to vaccinate all children in a target age range and geographical locality within a short period of time (often a day, a week or a month). Campaigns may be used to supplement routine programs (either as a one-off or as a method of giving a second dose) or as an alternative to them. They are often favored in countries that do not have the infrastructure to maintain a high coverage through routine vaccination program, but they are now also used in industrialized countries where it becomes necessary to quickly reduce susceptibility in a particular age group (Gay 1996).

The advantage of a suitably targeted campaign is that it removes most of the susceptible individuals from the population, thus reducing the reproduction number R well below the $R = 1$ threshold. This has a dramatic effect on transmission which may be interrupted if sufficient coverage is achieved. The follow-up program must maintain herd immunity, either through routine immunization or through periodic campaigns. If the latter approach is chosen, the interval between follow-up campaigns should be determined so as to maintain $R < 1$. A campaign is needed whenever the herd immunity threshold is about to be exceeded. Serological surveillance data enable a campaign to be targeted to maximal effect.

This basic strategy is behind the WHO's attempt to eradicate polio, and the attempt of the Pan American Health Organization to eliminate measles from the Americas (de Quadros et al. 1996). The elimination of measles through mass campaigns was pioneered in the Gambia in 1968–1970, based on modeling simulations by Macdonald (Thacker and Millar 1991), and revived in Cuba (Sabin 1991). Elimination of measles from the Americas may pave the way for eventual eradication.

OUTBREAK CONTROL

Outbreak control is a key activity for many types of infections. The techniques and tools that can be used are various and are dependent on the infection and its characterization though it needs to be recognized that the evidence base for a number of the older and more established infections are not as well established as they are for more recently described infections (Tables 1–4). For vaccine-preventable diseases, it may be used to complement or even replace mass vaccination programs when disease incidence is low. However, it is only suitable for infections where outbreaks can be identified at an early stage and/or where the infection is not highly transmissible (a low R_0), so that control measures can be taken before widespread transmission occurs. This requires that cases can be diagnosed rapidly and reasonably accurately (preferably clinically, and there is likelihood that measures are likely to be successful, i.e.

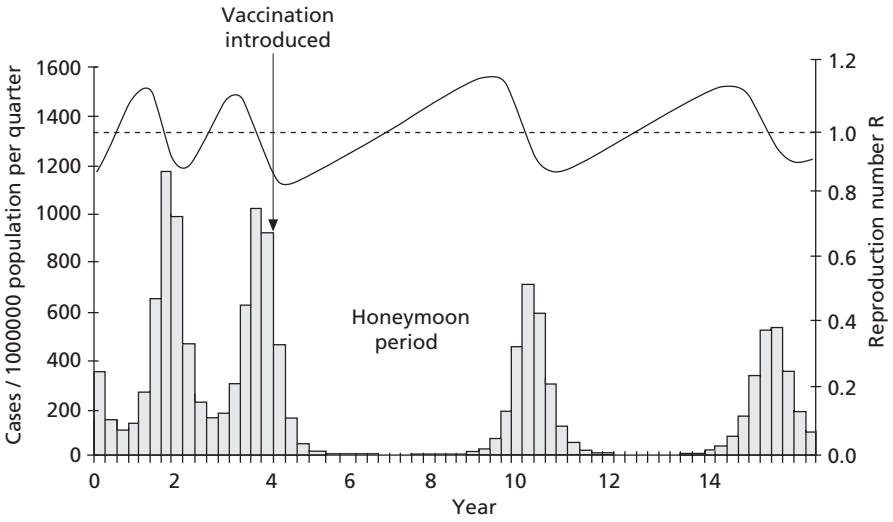

Figure 7 *Modeled number of cases of infection following the introduction of vaccination (for details see Figure 6)*

Table 4 *Techniques used for outbreak control*

Control techniques

Monitoring application of control measures
Monitoring effectiveness of control measures
Communicating with the authorities, media, and public

without needing laboratory confirmation) and that asymptomatic infections are uncommon. Low transmissibility of infection and a long latent period are also advantageous as they cause outbreaks to develop slowly, permitting time for interventions. As always, the control measures must be acceptable to the population and be within the law.

Aggressive outbreak control was an integral part of the smallpox eradication strategy and for the control of SARS; as both satisfy all the above criteria. However, attempts in the United States to control outbreaks of measles through targeted vaccination proved largely unsuccessful (Davis et al. 1987). Infections for which vaccine is currently used to control community outbreaks include hepatitis A, although it is not ideally suited to such an approach due to the high proportion of subclinical infections, but the low incidence of disease in the population does not justify the expense of mass vaccination.

QUARANTINE AND ISOLATION

Quarantine means to isolate or control the behavior of healthy people who are thought to have been exposed, are probably or possibly infected, and are in the incubation period (Heyman 2004). A quarantine strategy may be used to prevent the introduction of an infection into a population from which it is absent. It is only appropriate if the population is isolated from the potential source of infection. No attempt is made to create herd immunity in the population, so a failure of the quarantine measures could lead to a sizeable outbreak. Quarantine policies should therefore be backed up by outbreak control procedures. Quarantine measures were used extensively in North America in the nineteenth century to prevent ships from Europe introducing infections, such as cholera, smallpox, and typhus. They are still used to exclude rabies from the UK and are part of plans to control viral hemorrhagic fevers (Department of Health 1996). They are also a key part of emergency plans if smallpox should re-emerge and during the 2003 SARS outbreaks were used in some affected areas (Centers for Disease Control 2002; WHO 2003).

Isolation is generally taken to mean separating symptomatic infectious persons from those who are susceptible, as a policy can only be successful if infectives are identifiable and identified before they transmit infection.

CASE-FINDING AND SCREENING

Case-finding is essential to isolation and caring for those infected. However, it is also used more widely in controlling infections where identification contributes to interrupting transmission. It requires that cases are readily identifiable – some diseases, like SARS, pose difficulties because of the problem in distinguishing cases from other diseases causing similar symptoms (WHO 2003).

Case-finding is considered an important part of the strategy to control HIV transmission in industrialized countries where it is used to effect behavior change amongst those infected so as to make them less likely to pass on infection. Another example is when there has been health care worker infections for hepatitis B or C whilst undertaking exposure-prone procedures.

Screening is a special form of case-finding where it is considered useful to test particular population groups for specific infections (Table 4). It may be systematic or opportunistic (testing patients who are attending medical care for another purpose) and usually has to conform to the guidelines applied to screening (Calman 1994). An example of systematic screening is the testing of all pregnant women for infections they may transmit to their babies and for rubella immunity. Donor screening is used to ensure infections are not transmitted to recipients of blood and tissues.

Herd immunity and vaccination programs

Most communicable diseases have a regular cyclical pattern (Noah 1988). The interval between epidemics is determined by the rate at which susceptibles accumulate in the population. If epidemics occur in regular cycles it is possible to predict in advance when the next epidemic will occur. For example, pertussis epidemics in the UK have occurred at 4-year intervals. Other infections are less predictable. Epidemics of meningococcal disease occurred during both world wars, in the early 1970s, and again since the mid-1980s. Influenza epidemics are even less predictable and are associated with major antigenic shift in the influenza virus (see the *Virology* volume in this series). In general, the epidemic cycles of viral infections are more regular than bacterial diseases.

Introducing a vaccine which protects against transmission of infection disrupts the natural epidemic cycle of a disease. Models which simulate the transmission of infection within a population may be used to predict the effects of vaccination programs on the incidence of disease. The predictability of epidemics has been greatly enhanced in recent years by serological surveillance, where the proportion susceptible to an infection by age is determined through large cross-sectional antibody prevalence studies. In the UK, routine serological surveillance for measles, mumps, and rubella antibody was established in 1987, prior to the introduction of combined measles, mumps, rubella (MMR) vaccine (Morgan-Capner et al. 1988) using the unlinked-anonymous technique. The recent application of mathematical models to serological surveillance data enabled the anticipation of a measles epidemic in the UK which was averted by a national immunization campaign (Gay et al. 1997) (see later under Measles: vaccination strategy in England and Wales). Data from other serological surveillance contribute to the control of many other infections (Nicoll et al. 2000; Osborne et al. 2000).

Diphtheria

Diphtheria is an example of an infection where the use of high herd immunity has changed over time. The symptoms of diphtheria are caused by the production of an exotoxin which is produced by the infecting organism, *Corynebacterium diphtheriae*. Naturally acquired antitoxic immunity provides protection which is usually lifelong. The traditional method for measuring diphtheria immunity – the Schick test – is no longer available and has been superseded by the assessment of neutralizing antitoxin in serum. A level of 0.1 units of antitoxin per ml or greater indicates long-term immunity. In the prevaccination era, most babies were born with maternally derived natural immunity, and infection was relatively uncommon in the first year of life. Attack rates were highest in the 1–5 year age group and by early adulthood most individuals were immune to diphtheria (Figure 8).

Close contact is required for transmission of diphtheria and therefore epidemics occurred particularly under conditions of crowding and poor hygiene. The importance of closeness and duration of contact in determining the spread of disease was first described by Dudley in 1926. Children sleeping in the same school dormitory were at greater risk than those in casual contact during working hours. In temperate countries, the disease was most common in the colder winter months, whereas in tropical countries transmission occurred all year round. In tropical countries, the principal source of infection is from cutaneous diphtheria lesions, whereas in temperate countries pharyngeal diphtheria was more common.

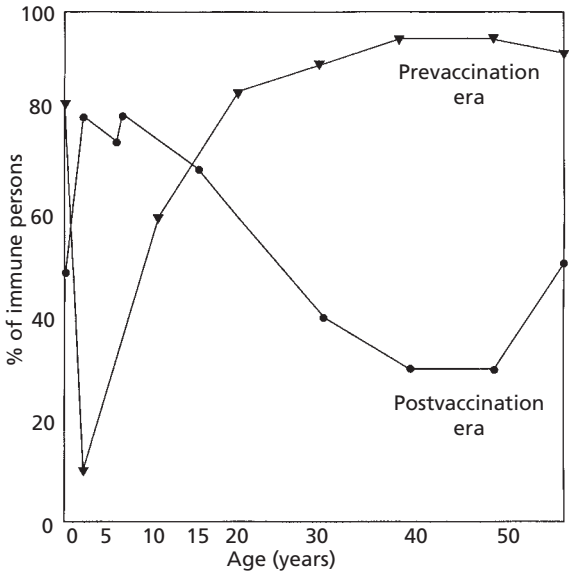

Figure 8 *Diptheria immunity by age in the pre- and post-vaccine eras*

Routine immunization with diphtheria toxoid (which protects against the toxic effects of the disease) was introduced in the 1940s. Immunization very rapidly reduced disease incidence in these countries and by the 1960s diphtheria had virtually been eliminated. As a result, the pattern of immunity in the population has changed completely. Because the organism no longer circulates in the community, adults born since the introduction of immunization rely solely on vaccine-induced immunity, which is generally lower than naturally acquired immunity. Immunization is commenced at 2 months of age so young infants very rapidly acquire vaccine-induced immunity, which is boosted by further immunizations given at school entry and (since 1993) on leaving school. However, older adults, in whom the last dose of vaccine was given many years ago, have waning immunity and up to a third of older adults may now be susceptible to diphtheria in Britain (Maple et al. 1995). Fortunately, this immunity gap does not appear to have led to significant outbreaks despite the fact that cases of toxigenic diphtheria continue to be imported from resource-poor countries (Begg and Balraj 1995). In the states of the former USSR, diphtheria re-emerged in the 1990s. This is only partly explained by waning immunity in adults. Other factors include mass population movements and lower vaccine coverage in young children.

Because vaccine-induced immunity protects against the toxic effects of the disease, one might expect that diphtheria immunization would not reduce circulation of the organism. Nevertheless, isolation of a toxigenic strain of *C. diphtheriae* is very rare nowadays, therefore it appears that vaccine does interrupt transmission as well as prevent disease. This is probably related to the fact that transmission of *C. diphtheriae* is much more efficient from symptomatic cases than from subclinical

carriers. The level of diphtheria immunity in the population that is required to achieve herd immunity is not known precisely, but is generally considered to be between 70 and 90 percent (Simonsen et al. 1987).

Pertussis

Immunity to pertussis is complicated, and many components of *Bordetella pertussis* appear to have a role. At present the serological correlates of immunity are not known, thus population immunity data are of little value in mathematical modeling.

In Britain, pertussis epidemics occurred at 4-year intervals before the introduction of routine immunization in the 1950s (Figure 9). There were over 100 000 reported cases a year and about 1 per 1 000 patients died from the disease. The mortality rate and the risk of complications from pertussis is greatly dependent on age. Most deaths occur in young children under the age of 6 months. After this age the severity of the disease declines progressively and in adults it may be a milder, self-limiting though long-lasting illness. Because the risk of severe disease is greatest in the first few months of life it is important that pertussis vaccines are given as early as possible. For this reason, an accelerated schedule of immunization, at 2, 3, and 4 months of age, was introduced in the United Kingdom in 1992.

Whole call pertussis vaccines were introduced in the 1950s. Coverage was initially high (over 80 percent) and the magnitude of epidemics decreased considerably. In 1972 only 2 000 cases were recorded. However, in the mid-1970s doubts were cast over the safety of the vaccine and vaccine coverage dropped from 80 to 30 percent. This led to a resurgence in epidemics, the size of which had not been seen for over 20 years. Subsequently, vaccine coverage has improved and the epidemics have again decreased in size. In 2000, only 883 cases were notified in England and Wales, the second lowest annual figure ever recorded (the lowest was 712 in 2000).

The interesting feature throughout this period is that despite the introduction of vaccine with great

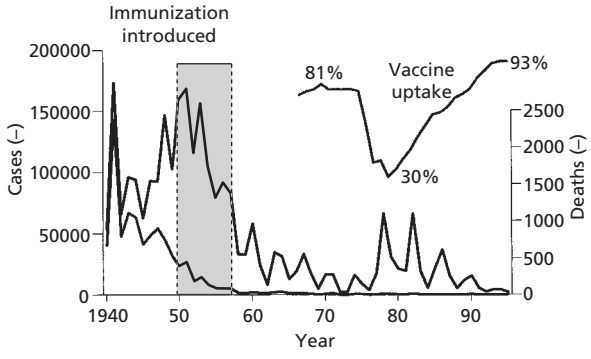

Figure 9 *Whooping cough notifications: cases and deaths, England and Wales 1940–1995 (prepared by CDSC; source OPCS)*

fluctuations in coverage there has been little change in the length of the interepidemic cycle. This led to the suggestion that pertussis vaccine may have no effect on carriage, but simply protects against disease (Fine and Clarkson 1982b). However, a decrease in the incidence of pertussis in children too young to be vaccinated points to some reduction in transmission (Miller et al. 1994). A recent study, which used an age-structured model to simulate the transmission of pertussis in England and Wales, suggested that both these observations are consistent with vaccine reducing transmission by approximately 80 percent (Miller and Gay 1997). In this scenario, the recent improvements in coverage to more than 90 percent would lead to a discernible lengthening of the epidemic period and an increasing proportion of infections would occur in adults. There is increasing evidence that adults with clinically inapparent or mild infection may act as important reservoirs of infection.

The question of vaccine providing protection against the transmission of infection has important implications for the control of pertussis. If the current subunit vaccines do not protect against transmission then elimination of the infection would be impossible. It remains to be seen whether the recently developed subunit vaccines affect transmission. Some preliminary evidence suggests that they may do so. Field trials of efficacy have recently established the efficacy of acellular pertussis vaccines in infants from 2 months of age (Olin et al. 1997).

Rubella: the prevention of congenital rubella syndrome

Most cases of rubella present as a mild illness with rash. Infection in pregnancy, however, can cause congenital rubella syndrome (CRS), resulting in severe malformation of the fetus, including cataracts, deafness, and heart defects, and an outcome of death or severe handicap (Gregg 1941; Miller et al. 1982). The purpose of a rubella vaccination program is to reduce the number of cases of CRS by preventing infections in pregnant women. A number of different strategies has been used to achieve this goal since the vaccine became available in 1970. The risks and benefits of each vaccination program can be evaluated using mathematical models (Anderson and Grenfell 1986), enabling informed policy decisions to be taken.

Before vaccination was introduced in developed countries, rubella epidemics occurred every 4–5 years and the average age of infection was approximately 10 years. About 85 percent of the population experienced the disease by age 16, leaving 15 percent who remained susceptible to infection as adults. A significant number of infections in pregnancy and consequent cases of CRS resulted. In developing countries, rubella is acquired at a much younger age – almost everyone is infected as a

child and cases of CRS are uncommon. However, rubella vaccination may become necessary if social and environmental changes lead to a reduction in transmission rates.

POLICY OPTIONS

The number of rubella infections in pregnancy depends on the number of susceptible pregnant women and the risk of infection in pregnancy. Vaccination programs were designed to reduce the number of infections in pregnancy by reducing one of these contributing factors. The two main options of universal or selective vaccination are often termed the US and UK policies, respectively, after the countries in which they were originally used.

The universal policy

The universal policy was designed to eliminate CRS through the elimination of rubella in the population, achieved by a high vaccine coverage of all children at a young age. Susceptible pregnant women would be protected from infection by the herd immunity of the population.

The selective policy

The selective policy was designed to reduce the incidence of CRS by reducing the level of susceptibility among pregnant women, achieved by vaccinating girls only at age 10–14 and screening all pregnant women for rubella immunity. This would allow the virus to remain endemic, so that many girls would be infected and acquire immunity before they were vaccinated. Vaccination would serve to reduce the number of susceptibles. Further reductions could be achieved by screening pregnant women, and vaccinating those found to be susceptible before their next pregnancy.

RISKS AND BENEFITS

A universal policy offers the greater benefit (the elimination of CRS), but also entails more risk. If vaccination coverage is low, the number of infections in pregnancy may actually be increased by the vaccination program. Vaccination reduces the force of infection acting on the unvaccinated population, causing them to remain susceptible longer until they acquire infection at an older age. The number of susceptible pregnant women may increase. If the increase in susceptibility among pregnant women outweighs the reduction in the force of infection, more cases of CRS will occur. This occurred, for example, in Greece in the 1990s when a universal policy was incompletely implemented (Panagiotopoulos et al. 1999).

In contrast, a selective policy can only eliminate CRS with 100 percent coverage. The risk to susceptible pregnant women is not reduced by the vaccination program. However, the policy does not carry the risk of increasing the incidence of CRS; the reduction in the incidence of CRS is the same as the coverage achieved.

Anderson and Grenfell (1986) used an age-structured model to calculate the number of cases of CRS expected at different levels of coverage for each of the two policies. At the long term steady state under the universal policy, there was an increase in the number of cases of CRS for coverages less than 30 percent, but rubella and CRS were eliminated for coverage greater than 80–85 percent (Figure 10). If coverage exceeded 75 percent, the universal policy prevented more cases of CRS than a selective policy with the same coverage. Short-term dynamic simulations produced similar results.

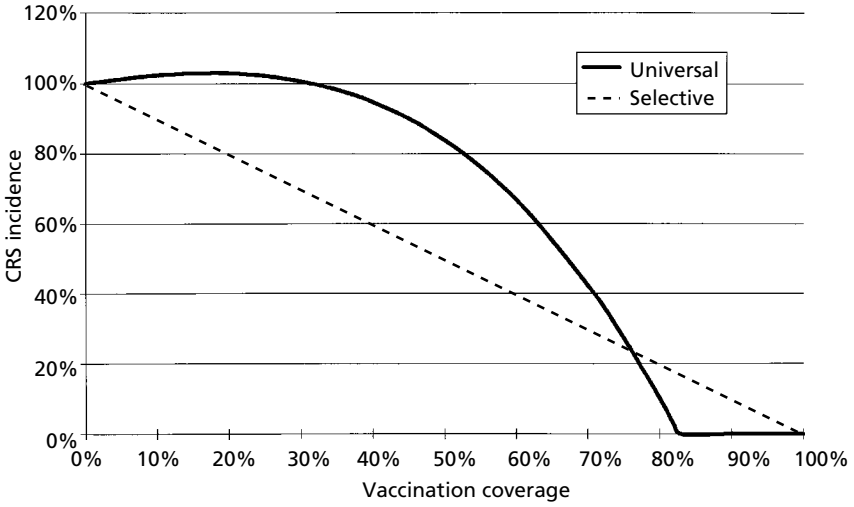

Figure 10 *Predicted equilibrium incidence of congenital rubella syndrome (relative to its incidence in the absence of vaccination) by vaccination coverage for selective and universal rubella vaccination programs (after Anderson and Grenfell 1986)*

Policy implications

The United States introduced a universal rubella vaccination program in 1969. Following a decline in the number of infections during the 1970s and 1980s to very low levels, a resurgence of rubella occurred in 1989–1991 (Lindegren et al. 1991; Centers for Disease Control 1994). Many cases were in unvaccinated young adults (including pregnant women; 56 cases of CRS were reported in 1990–1991) or in children from communities who refused vaccination. Since these outbreaks the incidence of rubella has returned to low levels. The US aimed to eliminate indigenous rubella and CRS by 1996, maintaining herd immunity through high vaccination coverage. To a large extent this has been successful with only 26 infants reported as born with CRS between 1997 and 1999 and 24 of these were in foreign-born mothers who are more likely to have missed out on immunization programs (Centers for Disease Control and Prevention 1994, 2001).

The UK introduced a selective vaccination program in 1970, and achieved 80–85 percent coverage at a time when the coverage of measles vaccination was less than 60 percent. Although this resulted in a considerable reduction in the number of infections in pregnancy, their continuing occurrence prompted a switch to a universal policy in 1988. A vaccination campaign amongst 5–16 year olds in 1994 removed many susceptibles from these cohorts, but in 1995 10–15 percent males aged 18–30 remained susceptible to rubella. This led to a resurgence of rubella in 1996, which included many outbreaks in universities and military barracks. The legacy of the selective vaccination program is that still in the mid-1990s less than 2 percent of women were susceptible to rubella, thus limiting the number of infections in pregnancy (Miller et al. 1996).

Sao Paulo State, Brazil, introduced a universal rubella vaccination program in 1992, following a modeling study to explore strategy options. This is an exemplary approach to vaccination program design. At the start of the program (in which vaccine is given to children at 15 months of age) a one-off vaccination campaign was carried out among older children to prevent the resurgent epidemics experienced in the US. The upper age limit of the campaign was set as 10 years as models suggested that little benefit was gained from including older children, despite the estimated seroprevalence in this age group being only 70–80 percent (Massad et al. 1994). The model's transmission rates were based on an age-specific force of infection estimated from a serological survey that included only 54 samples from persons aged 10 years or more (de Azevedo Neto et al. 1994). The experience of the next 10–15 years following the intervention will determine whether the decision not to include children aged 11–15 years in the campaign is an example of modeling saving unnecessary expenditure, or of too much faith being placed in the predictions of insufficiently robust models.

Measles: vaccination strategy in England and Wales

Measles is the most infectious of the vaccine-preventable diseases (Table 2) and causes significant morbidity and mortality if not controlled by vaccination. In this section we review the history of measles vaccination in England and Wales. In particular, we discuss the role of models in the planning of a national vaccination catch-up campaign conducted in 1994.

BACKGROUND

Measles vaccination was introduced in England and Wales in 1968. Before this time, measles epidemics occurred in alternate years causing an average of 100 deaths per year. Almost everyone experienced measles infection as a young child: 55 percent of notified cases were in those under 5 years, 42 percent in 5–9 year olds, and only 3 percent were in persons aged over 10 years. Vaccine uptake was initially low with only 50 percent of children being vaccinated up to 1980. Coverage then increased steadily reaching 80 percent by 1988. Over this period measles notifications and deaths showed a downward trend, but coverage was sufficiently low for the virus to remain endemic. Children who were not vaccinated became infected, resulting in continuing morbidity and mortality.

In 1988 combined measles, mumps, and rubella vaccine (MMR) replaced single antigen measles vaccine, following which coverage increased to 93 percent by the second birthday. This, together with an MMR catch-up program targeted at preschool children, resulted in a marked reduction in measles incidence in all age groups. Unvaccinated children, therefore, had little opportunity to acquire immunity through infection, and remained susceptible. The aging of cohorts with higher levels of susceptibility caused an increase in the proportion of school children who were susceptible to measles, detected through serological surveillance (Figure 11).

The shift of measles susceptibility was also reflected by a change in the age distribution of measles infections. A study using laboratory salivary diagnosis demonstrated that notifications (which are based on clinical diagnosis) were unreliable, especially in young children (Brown et al. 1994). Most infections occurred in persons aged 10 years or more and outbreaks in secondary schools were becoming more common (Ramsay et al. 1994; Calvert et al. 1994; Morse et al. 1994).

MODELING

Two separate approaches were used to predict the incidence of measles. Both models summarize their results using the reproduction number R. If $R < 1$, the population has herd immunity and no resurgence of disease can occur.

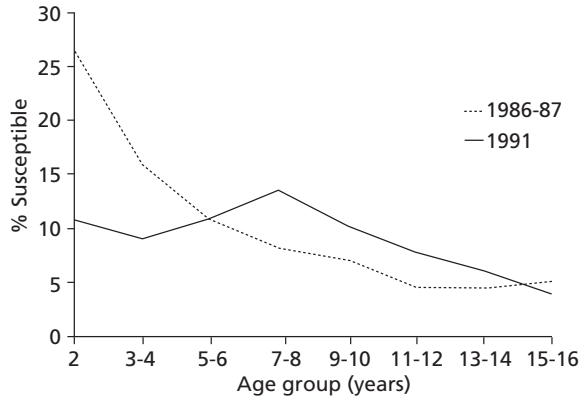

Figure 11 *Serological surveillance data: proportion of samples negative for measles IgG antibody by age, England 1986–1987 and 1991*

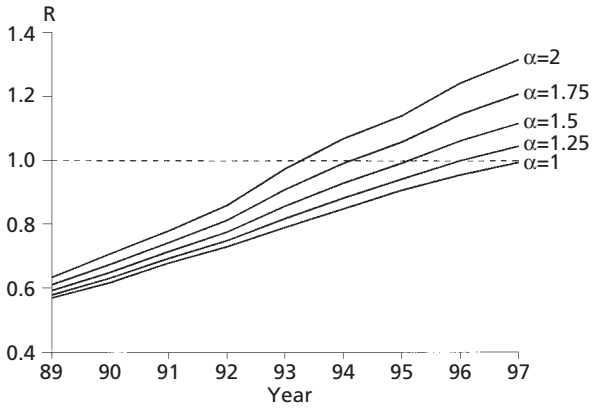

Figure 13 *Calculated value of the reproduction number for measles in England for a range of values of the age-specific transmission rates (Gay et al. 1995)*

The first study used models to interpret the serological surveillance data, to examine whether the increase in susceptibility would be sufficient to exceed the herd immunity threshold (Gay et al. 1995). The model divided the population into five age groups. The reproduction number is determined by the level of susceptibility in each age group and the transmission rates within and between age groups. (This calculation is the age-stratified equivalent of $R = R_0\, x$.) The level of susceptibility expected each year in each age group was projected from the serological data assuming no infection occurred. Transmission rates were derived from age-specific notification data from the prevaccination period (Figure 12). A range of values for the transmission rate within the 10–14 year age group was used due to the difficulty in obtaining a precise estimate. The model predicted that as the most susceptible cohorts moved into the age group with the highest transmission rates (10–14 year olds), the reproduction number, R, would exceed one. This would occur at some point before 1998, depending on the transmission rate assumed in the 10–14 year age group (Figure 13). The scenario that best reflected the observed changes in the age distribution of cases suggested that this would occur sooner rather than later. This provided the potential for a resurgence of measles in 1995/1996 involving more than 100 000 cases with most occurring in persons aged 10 years or more. Such a resurgence would have resulted in a high level of morbidity and mortality, because of the severity of measles in older age groups.

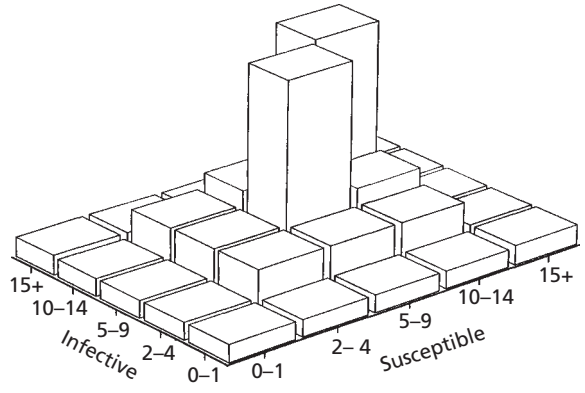

Figure 12 *Age-specific transmission rates for measles in England and Wales (with α = 1) (Gay et al. 1995)*

The second study simulated measles transmission in England and Wales using a dynamic model fed with vaccination coverage statistics (Babad et al. 1995). The model provided a good reflection of historic data. The study concluded that a single dose vaccination policy would not be sufficient to eliminate measles and investigated the options for supplementary vaccination measures. A vaccination campaign covering all children aged 5–16 years would reduce R well below the threshold. The introduction of a second routine vaccine dose at age 4 years, immediately after the campaign, would maintain the herd immunity of the population.

EFFECT OF THE CAMPAIGN

A national catch-up campaign to immunize children aged 5–16 with a combined measles and rubella vaccine was carried out in 1994 (Miller 1994). All children were offered vaccine, irrespective of a previous history of vaccination or disease; 92 percent coverage was achieved. The incidence of measles dropped dramatically following the campaign and the few cases that have occurred are in a pattern consistent with limited spread from imported infections (Gay et al. 1997). The introduction of a second dose into the routine vaccination schedule at school entry should sustain the herd immunity achieved. Continued surveillance is essential to monitor the effect of the program: salivary investigation of all suspected cases enables outbreaks to be identified; serological surveillance monitors the maintenance of herd immunity. Probably the most damaging impact on immunization for measles and mumps have been continuing controversies, much as two decades earlier similar

stories were for pertussis. Though there has been a decline in uptake of MMR in the UK, the fall is much less than that seen for pertussis (Gangarosa et al. 1998; Nicoll 2001; Miller 2003).

ENVIRONMENTAL AND SOCIAL EFFECTS AND POPULATION IMMUNITY

Changes in environmental and social conditions may affect the population in a number of ways. Poor hygiene facilitates spread of gastrointestinal infections, such as dysentery, by the fecal–oral route. Crowded accommodation facilities spread airborne infections, such as tuberculosis and meningococcal disease. Excessive throughput of patients in hospital makes it difficult to attend to infection control and control outbreaks. Temperature and other environmental conditions affect the survival of infectious disease agents. Social conditions, such as sexual behavior, and patterns of occupation influence the likelihood of being exposed to specific infectious agents (Hawker et al. 2001).

Control of disease by hygiene

In populations and settings where hygiene is poor, enteric infections spread easily. In settings such as refugee camps and following natural disasters, intense outbreaks may occur. For example, hepatitis A is endemic in many developing countries where basic hygiene measures such as hand washing and safe disposal of sewage are lacking. Most children become infected in the first few years of life. In this young age group, a large proportion of infections are subclinical and icteric cases are relatively uncommon. Where hygiene is good, infection in young children is relatively uncommon and most reach adulthood with no immunity to hepatitis A (Figure 14). In these countries, most infections occur in adults, at which age symptomatic infection is very common. Two main patterns of disease are observed – slowly evolving community outbreaks lasting for months or even years in which infection is transmitted from person-to-person and explosive point source outbreaks arising from a contaminated food or water source (Tang et al. 1991). Countries in the transition between the highly and lowly endemic states often experience a rapid reduction in the incidence of infection (Perez-Trallero et al. 1994; Lim and Yeoh 1992; Yap and Guan 1993). Models suggest that this may be followed by a substantial resurgence of endemic disease (Gay 1996).

Hepatitis A vaccines have recently become available and are of value in protecting those who are likely to be most at risk, such as travellers to highly endemic areas. No country has yet implemented hepatitis A for routine use (largely on the grounds of cost), however vaccines against hepatitis A, which could be incorporated into other vaccines as combination products, are being developed. In countries with good hygiene, the basic reproduction number for hepatitis A is relatively low (approximately two in England and Wales; Gay et al. 1994) and herd immunity could be achieved with modest vaccination coverage. However, mass vaccination programs may be most appropriate for countries in the transitional phase.

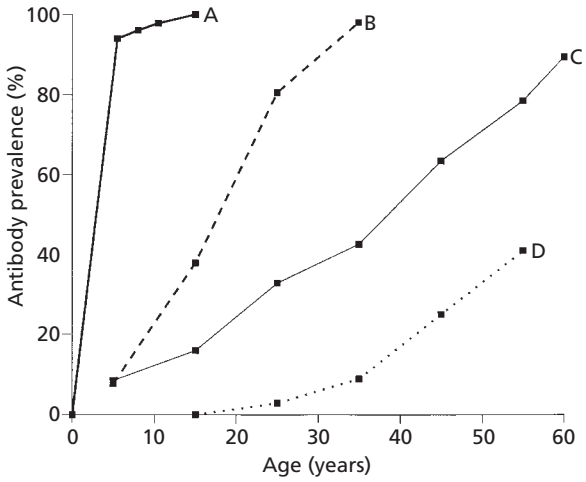

Figure 14 *Prevalence of antibody to hepatitis A in several countries: A, Cameroon, 1989 (Stroffolini et al. 1991); B, Spain, 1986 (Perez-Trallero et al. 1994); C, England, 1987 (Gay et al. 1994); D, Sweden, 1977 (Iwarson et al. 1978)*

Poliomyelitis is another example of a disease that is affected by changes in hygiene. During the early part of this century, when hygiene was poor in Britain, polio circulated widely among preschool children. In this age group paralysis was relatively uncommon and therefore the number of paralytic cases was small. During the 1940s and 1950s, as hygiene improved, and the circulation of wild virus diminished, the average age of infection rose. This led to epidemics of paralytic disease in older children and young adults (Figure 15). Polio vaccines became available in the 1950s, and rapidly reduced the incidence of the disease. Global eradication of polio is now planned by the World Health Organiza-

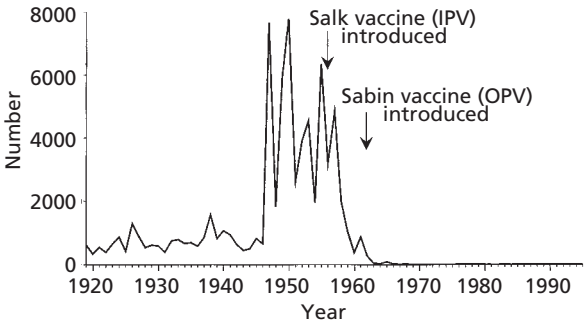

Figure 15 *Poliomyelitis notifications, England and Wales 1919–1995 (prepared by CDSC).*

tion. Eradication of polio is feasible, as there are no known nonhuman reservoirs of the disease, the virus does not survive long in environmental sources, such as sewage, live oral vaccine is able to both interrupt transmission as well as prevent disease, and is relatively cheap and easily delivered. However, at present (2004), it is proving difficult to achieve elimination in some countries experiencing civil strife and certain other populous countries, such as India and Nigeria (WHO 2004a).

Hospital hygiene is a major driver of health care-associated infections, though other factors come into play including surgical techniques undertaken as well as the level of dangerous pathogens in the surrounding population.

Sexually transmitted diseases and blood-borne viruses

Sexually transmitted diseases are an example of infections whose incidence is affected by behavior. The incidence of a disease is affected not only by the mean rate of partner acquisition, but especially by the degree of heterogeneity in behavior within a population. The importance of core groups (groups accounting for disproportionately large amounts of transmission) in the transmission of infection is well documented (Yorke et al. 1978; Jacques et al. 1988). Changes in the behavior of the core groups or their contact with noncore groups can have a dramatic effect on the incidence of infection and close attention to core groups is important for any STI control program.

Core groups are not the same in every country. In industrialized countries, men who have sex with men (MSM) are often important, while in resource-poor countries female sex workers often have a greater role though it may be that MSM are present, but not recognized because of severe stigma. Not all STIs conform to a pattern determined by core groups. Transmission of chlamydia and human papilloma virus (genital warts) is mostly accounted for by contact in the general sexually active population, especially among young adults. Control of STIs has to be through case-finding and treatment and effecting behavior change, including condom use (Mayaud et al. 1997; Samuel et al. 1991; Wawer et al. 1999; Cohen 1995). The blood-borne viruses, hepatitis B and C and HIV, follow a similar pattern of transmission to the STIs, but in addition are spread by equipment sharing among injecting drug users. Control is through prevention of drug injection, targeted promotion of safer injecting (needle exchanges, etc.), and treatment of those addicted.

The studies of gonorrhea by Yorke et al. (1978) and Hethcote and Yorke (1984) were the first detailed investigations of the transmission dynamics of a sexually transmitted disease. They described how changes in behavior affected the level of endemic disease. Since the mid-1980s the public health priority of controlling the HIV/AIDS epidemic has produced explosive growth in the literature. However, the complexity of the interactions between subgroups of the population and the problem of collecting suitable data from which to estimate parameters make modeling particularly difficult. Population-based surveys (Johnson et al. 1992) have provided a basis for initial parameter estimates. However, transmission models remain most useful for assessing the relative contribution of various factors to future trends in the incidence of AIDS, rather than for making quantitative predictions (Williams and Anderson 1994). STI control programs have shown how control of one bacterial infection can in some circumstances reduce transmission of a viral infection, HIV (Wasserheit 1994; Grosskurth et al. 1995; Cohen 1995).

Environmental infections

Some important infections persist in the environment and this is the key to their control. For example, Legionnaires' disease is a persistent problem in large buildings and requires scrupulous attention to water regulations (Giesecke 2002). For other infections, environmental spread via food, water, or the air means careful attention to water sources and food distribution chains are required (Hawker et al. 2001). In these infections par excellence contributions by social scientists and modelers have become crucial to understanding spread and devising control methods (Garnett et al. 1999; Hahn 1991; Klovhdah 1985; Robinson et al. 1995; Morris and Kretzschmar 1997; Schinazi 2001).

Vector control

A variety of infections are transmitted indirectly through vectors, such as insects. One of these, malaria, was the first infection in which population dynamics were studied extensively. Transmission of malaria depends on several factors, but the most important relate to the anopheline mosquito vector. The calculation of the basic reproduction number and eradication threshold are different with reference to vector-borne infections than to directly communicable infections. The contact parameter is a function of the density, survival rate, and feeding behaviors of the vector populations. The estimates of the basic reproduction number for malaria range between 5 and 100. These reflect considerable variations in the epidemiology of malaria, which is observed even within relatively small geographic areas. Macdonald developed a formula for the likelihood of infection based on the proportion of anopheline mosquitoes with sporozoites in their salivary glands. Malaria transmission in Macdonald's model was proportional to the density of the vector, the number of times each day

that the mosquito bites man, and the probability of the mosquito surviving for 1 day. Macdonald's model has been refined in recent years, but it does illustrate certain important points relevant to the control of malaria. Vector longevity is the most important factor in determining transmission and therefore focuses control measures on the adult mosquito. Control programs are most likely to be effective where vector longevity is short and the basic reproduction number is low. This was the situation in Europe where the reproduction level was low in many areas and the vector was found mainly inside houses where it could be attacked with insecticides. There is also considerable variation between different species of anopheline mosquitoes with respect to their ability to transmit malaria (the vectorial capacity). Each vector has its own behavior patterns and breeding grounds. Malaria is often seasonal, coinciding with the rainy season which provides water for mosquito breeding and increased humidity favoring mosquito survival.

Vector-borne human infections are not confined to tropical countries and there are many other organisms that are spread by mosquitoes (Ludwig and Cooke 1975). West Nile virus has, since the late 1990s, appeared and spread extensively from east to west across the USA and is proving very difficult to control (Granwehr et al. 2004).

Current malaria control strategies focus on protecting individuals against bites (bed-nets, etc.) or disease (human chemoprophylaxis). These are not very successful at a population level. Several malaria vaccines are currently under development and these may have individual, as well as population, actions. They are being designed to act at various stages of the cycle of infection. Some of the candidate vaccines may only protect against transmission and not against disease.

GENETIC FACTORS IN POPULATION IMMUNITY

Studies of herd immunity must clearly take into account genetic differences in resistance. Much of the work in this area was done on mice in the 1920s developing so-called Webster mice. These workers were able to show genetic effects in resistance to infection which emerged as a result of inbreeding and other genetic manipulations. The extent to which this work can be extrapolated to man is not clear. Observations in human populations are beset by confounding factors. There is no doubt that some populations are more susceptible to certain infectious diseases than others. Of particular note is the fact that there are sex differences in disease attack rates for many childhood infectious disease, for example mumps is more common among boys than among girls. The incidence of meningococcal disease and other infections caused by bacteria with polysaccharide capsules varies enormously in different parts of the world. Certain populations, for example Australian Aboriginal, have very high rates of disease and respond less well to polysaccharide vaccines than white children (McIntyre et al. 2000).

ZOONOSES AND EMERGING INFECTIONS

A number of the most important human infections have their origins in animals which either act as a continuing reservoir of infections (e.g. salmonellae, *Escherichia coli* O157), or were the original source, but now transmission is established between humans (HIV, measles). For the former, theories of transmission and control rely on animal husbandry, as well as on protecting humans. For example, some countries have been very successful in reducing levels of salmonellae pathogenic to man through vaccinating chicken flocks (Methner et al. 1999).

Zoonoses contribute disproportionately to the continuing stream of emerging infections that threaten human health. Many of these infections are of limited consequence, but a small number, such as HIV, the new viral hemorrhagic fevers, multidrug resistant organisms, and West Nile virus, has posed major threats. These infections require control measures which have to be based on good theoretical work tested against rapidly gathered data. The rapid institution of control measures against SARS shows how modern laboratory and epidemiological science can quickly combine even with an atypical and novel infection (WHO 2003; Anderson et al. 2004). Equally the persistent threat and near occurrence of pandemic influenza from avian influenza in domestic fowls as far away as China and as near as the Netherlands indicates no scope for complacency (WHO 2004b).

Societal changes	2	Infectious origins of chronic diseases	7
Changes in technology	3	Summary	7
Land-use patterns and ecological change	4	References	7
Microbial adaptation and change	4		

In recent years, the world has witnessed an emergence and resurgence of infectious diseases. Despite predictions earlier in this century to the contrary, infectious diseases remain the leading cause of death in developing countries, and the potential threats posed by infectious diseases are increasing (Institute of Medicine (IOM) 1992, 2003). The factors contributing to the emergence of infectious diseases are multiple and complex. They include demographic changes, changing lifestyles, political instability, unprecedented global travel and commerce, development of new technologies, ecological changes, microbial adaptation and natural variation or mutation of microorganisms, deterioration of national and international infrastructures for the control of infectious agents, and intent to do harm. These factors may contribute to the emergence of a wide array of microorganisms, including bacteria, viruses, parasites, and fungi.

As broadly defined by the 1992 US Institute of Medicine report, *Emerging Infections: Microbial Threats to Health in the United States*, emerging infections are those whose incidence in humans has increased within the past few decades or whose incidence threatens to increase in the near future. These include the emergence of new agents, the re-emergence of agents that previously had declined in incidence, and the development of antimicrobial resistance. The term also includes the recognition that an established disease has a previously unknown infectious origin.

DEMOGRAPHIC CHANGES

Increasing population density and urban poverty in many areas of the world are major factors favoring the emergence and re-emergence of diseases such as tuberculosis, shigellosis, and cholera. The population of the world, less than two billion at the beginning of the twentieth century, exceeded six billion by the end of the century and by the year 2050 is expected to grow to between 7.3 and 10.5 billion (Figure 1) (Rousch 1994; Lutz and Qiang 2002).

Along with the population surge, the geographical distribution of the world's population is shifting. Since 1950, an increasing percentage of people are living in Asia and Africa. It is predicted that Africa's percentage of the world's population will continue to increase, from 12 percent in 1990 to 23 percent by the year 2050 (Rousch 1994). In turn, the percentage of the world's population living in Europe or North America is declining. There is also a dramatic trend towards urbanization, with most of the population increase expected between 2000 and 2030 to be absorbed by urban areas in developing countries. By the year 2015, the United Nations (2001) projects that six cities will have 20

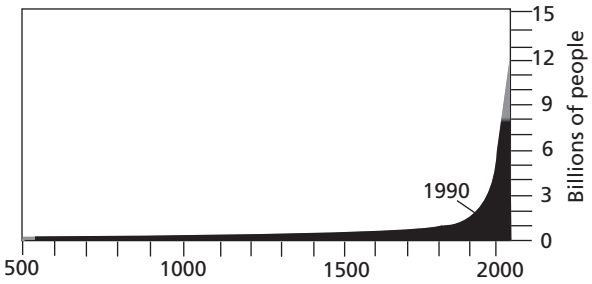

Figure 1 *World population through 1990, with projections by United Nations demographers of high and low scenarios. (Abstracted with permission from Roush, 1994. Copyright 1994 American Association for the Advancement of Science.)*

million population or more, including Tokyo, Dhaka, Mumbai, Sao Paulo, Delhi, and Mexico City. Overcrowding and development of slum areas are growing factors in a complex set of interactions that contribute to disease emergence.

INTERNATIONAL TRAVEL AND COMMERCE

The dramatic increases in international travel and commerce are also playing a significant role in the emergence of infectious diseases. The current volume of global traffic, together with the speed at which destinations can be reached, is unprecedented. In 2000, the number of international trips on commercial airplane flights was estimated to reach nearly 700 million (IOM 2003), and flights carried people with drug-resistant tuberculosis, cholera, and other diseases. Occasionally, the transport vehicles are themselves the sites of dissemination of disease, as with legionnaires' disease on cruise ships (Centers for Disease Control and Prevention (CDC) 1994c; Castellani et al. 1999) or food-borne illnesses or tuberculosis on airlines (Driver et al. 1994; Hedberg et al. 1994; CDC 1995c).

There are many examples of human movement resulting in geographical dispersion of a pathogen; recent advances in molecular epidemiology have been instrumental in documenting the course of a number of pathogens. In the early 1980s, a pneumococcus multiply resistant to penicillin, tetracycline, chloramphenicol, and trimethoprim-sulphamethoxazole was described in Spain, and its spread to the USA was documented in 1992 (Munoz et al. 1991), South Africa in 1994 (Klugman et al. 1994), and South Korea in 1997 (McGee et al. 1997). It is now recognized as a global clone (McGee et al. 2001) and the contribution to this single clone to the burden of penicillin-resistance is remarkable – in three studies, this clone alone comprised 39 percent (Corso et al. 1998), 16 percent (Gherardi et al. 2000), and 18 percent (Richter et al. 2002) of all penicillin-resistant strains from multiple geographic sites across the continental USA. Recently this clone has acquired resistance to the fluoroquinolones. In Hong Kong, which has the highest rate of fluoroquinolone resistance in the world, all the resistant strains belonged to this single clone (Ho et al. 2001).

In the early 1990s, an estimated 20 million people were refugees, a group that may be at higher risk of many infectious diseases (Wilson 1995). More recent estimates are even higher (Summerfield 1997), and tuberculosis, *Shigella*, and cholera are among the diseases causing deaths among refugees. Drug-resistant tuberculosis has been common among refugees entering developed countries from developing countries and has contributed to the resurgence of tuberculosis witnessed in some developed countries.

Acute disasters such as earthquakes and displacement of people through civil strife, may have an impact on food and water supplies and often require temporary living quarters, which frequently resemble slums. Following civil strife in Rwanda in 1994, an estimated 50 000 Rwandan refugees died within the first month as cholera and *Shigella dysenteriae* type 1 swept through the camps in Zaire (Goma Epidemiology Group 1995). This strain spread widely down through Africa, associated with epidemic hemolytic-uremic syndrome (HUS) (Bloom et al. 1994).

Global commerce has also been an important factor in transporting pathogens. Importation of turtles, iguanas, and other reptiles carrying *Salmonella* (CDC 1995b), the carriage of *Vibrio cholerae* in the ballast water of ships, and shipment of fresh fruits and vegetables contaminated with *Shigella* or enterotoxigenic *Escherichia coli* from one geographical area to another (Hedberg et al. 1994) have resulted in outbreaks of disease geographically distant from the source of the pathogen (Wilson 1995).

Although most fruits and vegetables used to be grown and consumed locally, the increasing trend towards global commerce has led to expanded importation of fresh fruits and vegetables from developing countries into more developed countries, and workers within developed countries today are often low-paid migrant workers (Hedberg et al. 1994). These factors increase the potential for products to be contaminated in the field, during packing, and during distribution to retail markets and have contributed to the changes in the epidemiology of food-borne diseases, which has witnessed an increasingly wider array of pathogens including bacteria, parasites, and viruses.

Travel, migration, and commerce allow global mixing of microbial species. Disease emergence may occur if circumstances in the new environment are propitious, allowing survival and proliferation of an introduced microbial pathogen.

SOCIETAL CHANGES

Changes in individual and collective behavior can affect the risk of exposure to infectious agents. For example,

as the association was made between cardiovascular disease risk and consumption of selected foods such as beef, people changed their dietary habits, including the consumption of different food items. In the USA and many other developed countries, the per capita consumption of whole milk and beef declined, and consumption of cheese, poultry, and fresh fruits and vegetables increased (Hedberg et al. 1994). Changes in dietary habits continue as new issues emerge. The concern following the recognition of variant Creutzfeld–Jakob disease related to bovine spongiform encephalopathy led to an abrupt decline in beef consumption in some countries; at the same time, an inceased focus on addressing obesity in the USA has led to increases in the consumption of high-protein foods, including beef. The variety of food has also changed; compared with 50 years ago, a markedly increased number of items are stocked in the average grocery store in developed countries. The place of consumption has also changed; the number of fast-food restaurants has increased, as have such features as salad bars to accompany the changing dietary preferences.

The proliferation of fast-food restaurants with uniform methods of preparation and frequent use of single sources of food has further expanded the opportunities for a large number of people to be exposed to contaminated food. In an outbreak of HUS and hemorrhagic colitis in western USA caused by hamburger contaminated with *E. coli* O157:H7 (Bell et al. 1994), scores of restaurants affiliated with a single fast-food chain were implicated.

In some economies, there has been an expanding participation of women in the workforce and a rising proportion of single-parent families, accompanied by growth in the use of child-care services. In the USA, 90 percent of families with preschool children use full- or part-time child daycare services (Thacker et al. 1992). Because children are frequently in close or direct physical contact and have poor personal hygiene, pathogens may be transferred more readily from one child to another in these facilities. Use of child-care centers has been associated with an increased risk of transmission of many enteric and respiratory pathogens

Outbreaks of diarrheal illness in child-care centers have resulted from many enteric pathogens including *Shigella*, *Salmonella*, *Campylobacter*, and *E. coli* O157:H7 (Thacker et al. 1992). Children attending daycare centers are at a 1.6–3.4 times greater risk of having a diarrheal illness compared with children who receive care at home. The risk is greatest for those not yet toilet-trained. Secondary spread to household and community contacts may also occur.

The incidence of respiratory illnesses, including those caused by *Streptococcus pneumoniae* (Levine et al. 1999) and group A *Streptococcus* (Espinosa de los Monteros et al. 2001), is also elevated for children attending child-care centers. Accumulating evidence suggests that daycare attendees are at greater risk for acute otitis media, which often follows upper respiratory infections, than children cared for at home (Rovers et al. 1999; Baraibar 1997). Increased use of child-care centers may account partially for the marked increase in visits to physicians for otitis media documented in the USA between 1975 and 1990, from approximately ten million visits to over 24 million visits per year (Schappert 1992). Outbreaks of tuberculosis in family daycare homes have also been reported.

Changes in sexual behavior have also affected changes in disease patterns (Wasserheit 1994; Donova 2002). The rates of sexually transmitted diseases are closely associated with changes in the number of sexual partners, use of drugs and adequacy of health-care services. Recent increases in reported rates of chlamydial infection are related not only to improvement in surveillance but also to increases in sexual activity of very young women. High rates of oral contraceptive use may foster rapid transmission of chlamydial infection.

CHANGES IN TECHNOLOGY

Changes in technology have also resulted in the emergence of newly recognized pathogens. New methods of food production have led to new niches for pathogens. Mass production, with its increased complexity of operations, can greatly magnify the public-health significance of microbial contamination. A pathogen present in some of the raw material may contaminate a large batch of final product. For example, there have been dramatic changes in how hamburger meat is produced in the USA. Today, a single hamburger patty typically includes meat from many cattle, and cattle from many different farms (Boyce et al. 1995). Over a quarter of a million hamburgers contaminated with *E. coli* O157:H7 were recalled in one single outbreak (Bell et al. 1994; Berkelman 1994). Contaminated cheese from one plant distributed to four other processors, which subsequently shredded it and thereby contaminated cheeses from other sources, led to a widespread outbreak of salmonellosis (Hedberg et al. 1992).

Medical and technological advances in the medical care of patients have resulted in benefits to many patients, but many of these advances have also been accompanied by an increased risk of infections. The escalation in the use of chemotherapy, radiation, and other immunosuppressive therapy has increased the frequency of opportunistic infections. Bacteremias and fungemias associated with intravascular devices have increased dramatically (Edgeworth et al. 1999). Renal dialysis units expose susceptible patients and personnel to complex equipment that frequently is difficult to decontaminate (Favero et al. 1992). Surgery is performed on patients who are already highly susceptible to infections.

Special attention must be given to the risk of transmission of infection through transfusion of blood or blood products (Kuehnert et al. 2001; Walsh et al. 2002). In the USA, there has been an increase in the number of episodes of sepsis caused by *Yersinia enterocolitica*; prolonged storage of the packed red blood cell units have resulted in high bacterial and endotoxin concentrations in the transfused unit (Tipple et al. 1990; CDC 1991). In addition, there have been more reports of infections with staphylococcal species resulting in sepsis or death associated with contaminated platelets; most of these units were pooled units with long storage times (Zaza et al. 1994).

The use of organ transplants has also grown dramatically in many countries in the past decade. Organ transplants pose special risks: the organ may harbor a pathogen, and the transplantation procedure is accompanied by immunosuppressive therapy (Hibberd and Rubin 1992). The number of opportunistic bacterial, fungal, and other infections has also risen as a result of the emergence of human immunodeficiency virus (HIV). Although the advent of highly active antiretroviral therapy (HAART) has had a major impact on the burden of opportunistic infections in developed countries, these infections threaten to overwhelm health services in sub-Saharan Africa.

Legionnaires' disease has emerged in developed countries as a result of technological change. Cooling towers, air conditioners, whirlpool spas, respiratory therapy equipment, ultrasonic mist machines, and industrial settings in which aerosols are produced have all provided new opportunities for the *Legionella* bacterium to become aerosolized and infect humans (CDC 1994b, Fry et al. 2003).

Technology related to tampon development and use was associated with the emergence of menstrual-associated toxic shock syndrome. This illness is due to in vivo production of a unique toxin, toxic shock syndrome toxin-1, by *Staphylococcus aureus*, and the epidemic of toxic shock syndrome witnessed in 1980 was associated with the introduction and marketing of hyperabsorbable tampons. The molecular basis for increased toxin production in the presence of tampon fibers has been debated (Kass 1987).

LAND-USE PATTERNS AND ECOLOGICAL CHANGE

Ecological changes have contributed to the emergence of tick-borne diseases in many areas of the world. Lyme disease, caused by transmission of *Borrelia burgdorferi* through tick bites, has become the most common vector-borne bacterial disease in the USA, and reported cases of disease continue to increase. The disease is also well recognized across Europe and northern Asia; cases have also been reported from other continents (Berglund et al. 1995). Sites of intense transmission of *B. burgdorferi* often represent newly reforested areas that had been farmed recently. The suburban encroachment on the newly reforested areas, along with increased recreational use of forested areas, has also increased the exposure of humans to ticks.

Human ehrlichiosis was first described in the USA in the mid-1980s (Blanco and Oteo 2002; Dumler and Bakken 1995). *Ehrlichia chaffeensis* causes human monocytic ehrlichiosis, a syndrome characterized by fever, headache, and laboratory findings such as leukopenia and thrombocytopenia, and it may be life-threatening if untreated (Paddock and Childs 2003). It is primarily transmitted by the lone star tick, *Amblyoma americanum*. A closely related organism, *Anaplasma phagocytophilum* (formerly classified in the genus *Ehrlichia equi*), causes a similar syndrome known as human anaplasmosis (formerly human granulocytic ehrlichiosis). People affected in the USA have spent time in tick-infested areas where *Ixodes scapularis* and *Ixodes pacificus* are common. The European vector is the same as that of Lyme borreliosis, *Ixodes ricinus*.

Alterations in the aquatic environment may result in changes in the occurrence of waterborne diseases. The seasonality of cholera has been related to coastal algae blooms (Epstein et al. 1994). Other changes in human ecology, such as urbanization and the development of periurban slums, may also contribute to an increased risk of diseases such as cholera (Levine and Levine 1994).

Both long-term climate changes and weather have been shown to alter the risk of various infectious diseases. Heavy rainfall contributed to a large outbreak of leptospirosis in Nicaragua in 1995, with exposure of humans to flood waters contaminated by urine from infected animals, particularly dogs (Trevejo et al. 1998). El Niño provided unusual conditions that favored growth of *Vibrio parahaemolyticus*, which led to an outbreak of disease related to shellfish (CDC 1998).

The incidence of Buruli ulcer, caused by *Mycobacterium ulcerans*, has dramatically increased in West Africa in recent years (Dobos et al. 1999). The increase is attributed to environmental changes including regional flooding. The natural reservoir is unknown but suspected to be an environmental exposure, since many affected individuals live near slow-moving or stagnant water.

MICROBIAL ADAPTATION AND CHANGE

New pathogens may emerge as a result of a mutation causing enhanced virulence. Such a mutation may explain the emergence of Brazilian purpuric fever in 1984, caused by *Haemophilus aegyptius*; it was the first time that this agent had been shown to cause invasive disease (CDC 1985; Brazilian Purpuric Fever Study Group 1987). Since its recognition in Brazil, this virulent

pathogen has been found in Australia; other parts of the world may be at risk for epidemics.

In 1993, the clonal spread of a novel non-O1 serotype of *V. cholerae* was documented (Ramamurthy et al. 1993); *V. cholerae* O139 was first detected in southern Asia and quickly replaced *V. cholerae* O1 strains in many affected areas. Previous natural infection or receipt of cholera vaccine was found to afford little or no protective benefit.

The development of resistance to antimicrobial agents is also a powerful example of bacteria's capacity to adapt. Almost all major bacterial pathogens acquire antibiotic-resistance genes (Tomasz 1994) and the problem has been amplified by the increased use of antibiotics worldwide.

The introduction of penicillin in the 1940s was soon followed by the detection of resistant bacteria. Bacterial resistance has grown with the addition of large numbers of antibiotics with distinct mechanisms of action. These antibiotics have increasingly had a wider antibacterial spectrum. Antibiotics have been introduced not only for therapeutic use in people but also on a large scale in animal feed. Endtz et al. (1991) demonstrated the rise in prevalence of *Campylobacter* strains that were resistant to ciprofloxacin in both poultry products and in human stools in the Netherlands. Extensive use of fluoroquinolones in the poultry industry between 1982 and 1989 is likely to have resulted in the resistance observed. The ban of antimicrobials for growth promotion in Denmark has led the way to reducing resistance amongst enterococci in that country (Aarestrup et al. 2001).

Once genes for resistance have been acquired, the progeny of these bacteria with their resistance genes tend to spread with great rapidity within the species. Production of β-lactamase by staphylococci was rare before the introduction of penicillin. More than 90 percent of all isolates of *S. aureus* now carry the β-lactamase gene, in both the USA and Europe, and methicillin resistance increased rapidly in the 1980s. Strains with and without genes for resistance demonstrate similar virulence in terms of toxin production. Methicillin resistance is mediated most frequently by the production of a novel penicillin-binding protein. Noble et al. (1992) demonstrated conjugative transfer of high-level vancomycin resistance from *Enterococcus faecalis* to *Staphylococcus aureus* in the laboratory and raised concern that resistance may be transferred to wild-type *S. aureus*. The vancomycin-resistance determinant *vanA* has now indeed spread from the enteroccoccus to *Staphylococcus aureus* to create the first high-level vancomycin-resistant *Staphylococcus aureus* (VRSA) infections (CDC 2002).

The incidence of infections with vancomycin-resistant enterococci has also increased. These strains are now very common in intensive care units, and amongst dialysis units the proportion reporting a patient with vancomycin resistant enterococci (VRE) increased from 11.5 percent in 1995 to 32.7 percent in 2000 (Tokars et al. 2002). Spread of resistant strains within hospitals may be limited by aggressive infection control measures and prudent vancomycin use.

Drug-resistant *S. pneumoniae* was first documented in Australia in the 1960s and multiply resistant strains were reported in South Africa in the 1970s; reports of similar isolation were made with increasing frequency from other parts of the world in the 1980s. By 1998, 24 percent of pneumococcal isolates submitted to CDC were resistant to penicillin and 14 percent were resistant to at least three drug classes. The emergence of penicillin resistance in Europe has been correlated closely with antimicrobial use in those countries (Bronzwaer et al. 2002) (Figure 2). The rapid emergence of drug-resistant strains is complicating the management of pneumococcal infections and demonstrates the need for more judicious use of antimicrobial agents (Heffelfinger et al. 2000).

Penicillinase-producing *Neisseria gonorrhoeae* was first recognized in 1976. By the 1990s, 32 percent of *N. gonorrhoeae* isolates were resistant to penicillin or tetracycline, and resistance to fluoroquinolones was recognized (CDC 1993). Fluoroquinolone-resistant strains now have a global distribution. *N. gonorrhoeae* also demonstrates the increasingly diverse array of mechanisms of resistance, including both plasmid- and chromosomally mediated resistance to the penicillins and tetracyclines.

Antibacterial resistance is also a problem for the developing world. In central and southern Africa, isolates of *S. dysenteriae* 1 have been demonstrated to be resistant to all readily accessible oral antibiotics,

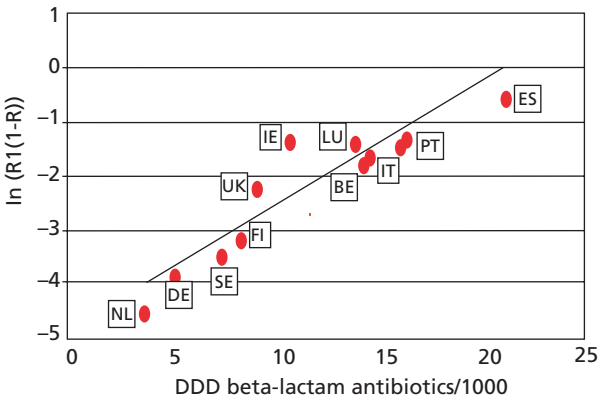

Figure 2 *Association of antibiotic use with resistance in* pneumococci*: The log odds of resistance to penicillin among invasive isolates of* Streptococcus pneumoniae *(ln R/(1-R)) is regressed against outpatient sales of beta-lactam antibiotics in 11 European countries. DDD, defined daily dose; BE, Belgium, DE, Germany; FI, Finland; IE, Ireland; IT, Italy; LU, Luxembourg; NL, the Netherlands; PT, Portugal; ES, Spain; SE, Sweden; UK, United Kingdom. (Redrawn from Bronzwaer et al. 2002, www.cdc.gov/ncidod/EID/vol8no3/01-0192.htm, with permission.)*

including ampicillin, chloramphenicol, nalidixic acid, tetracycline, and trimethoprim-sulphamethoxazole (Ries et al. 1994; Tuttle et al. 1995). The need to monitor, regularly and frequently, the prevailing antimicrobial resistance patterns in different geographical areas has been repeatedly demonstrated. Preventive measures may be more successful than therapy for control of many epidemics.

BREAKDOWN OF PUBLIC-HEALTH INFRASTRUCTURE

Complacency has also resulted in the re-emergence of pathogens previously controlled. Basic tenets of public health, such as close monitoring of disease in a population accompanied by a rapid response for diseases such as shigellosis and salmonellosis, and control programs for diseases such as tuberculosis and diphtheria, have been neglected in many areas of the world as public-health attention towards the control of all but a few selected conditions declined in the 1970s and 1980s (Berkelman et al. 1994). In addition, the emergence of new pathogens such as *E. coli* O157:H7 has been addressed inadequately.

Cases of tuberculosis in the USA increased 18 percent from 1985 through 1991; yet, by 1992, most public-health laboratories had not incorporated the more rapid radiometric methods for routine culture or drug-susceptibility testing of mycobacteria. The erosion of public-health services together with the mistaken perception of tuberculosis as a disease of declining public-health significance resulted in decreased funding for many laboratories in the USA and resulted in the delay in implementation of newer, more rapid diagnostic technologies for tuberculosis (Bloom and Murray 1992; Dowdle 1993; Huebner et al. 1993) as well as a decline in resources for control programs.

In 1994, reports of widespread transmission of pneumonic plague within India resulted in estimated economic losses to India of over $1 billion dollars (Campbell and Hughes 1995). Intense investigation revealed that most reported cases of plague were incorrectly diagnosed and that no transmission of pneumonic plague was identified in any major city except Surat. Effective surveillance coupled with laboratory expertise in plague might have averted some of the economic loss.

The epidemic levels of cholera reached in South America in the early 1990s, after almost a century of absence of the disease from the continent, were attributed, in part, to breakdowns in public-health measures (IOM 1992). Contaminated municipal water supplies contributed to the spread of the epidemic after the pathogen was introduced along the coastal waters of Peru (Blake 1993). As both the population and the percentage of the population in poverty grow in South America, the potential for spread of diarrheal illnesses increases.

In the early 1990s, Russia and many of the newly independent states experienced a dramatic resurgence of diphtheria (CDC 1995a) (Figure 3). Inadequate immunization of the population, crowding and low socioeconomic conditions, and high mobility of the infected individuals may have contributed to this outbreak, which has resulted in thousands of deaths. Also, from 1990 to 1995, tuberculosis rates in Russia increased by 70 percent, with more than 25 000 people dying from the disease each year (Netesov and Conrad 2001). The increased incidence has been compounded by the spread of multidrug resistant tuberculosis.

INTENT TO DO HARM: BIOTERRORISM

The growing threat of intentional attacks using biological agents is a serious one and must be addressed (IOM 2003). CDC has developed three categories of biological agents, prioritized according to their likelihood of bioterrorist use and the severity of the diseases they produce. Three of the six CDC category A (high priority) agents are bacteria or their toxins: *Yersinia pestis*, *Bacillus anthracis*, and *Clostridium botulinum* toxin. Outbreaks may occur as a result of natural occurrence, unintentional release by those working on these agents in laboratories, or intentional use. All of these agents have been weaponized to cause disease when released in aerosol form. Pneumonic plague, inhalation anthrax, and botulism may all occur naturally but are quite rare in developed countries today.

In 1979, an unintentional release of anthrax spores from a Soviet bioweapons facility caused an outbreak of inhalational anthrax, the largest recorded outbreak of inhalation anthrax, with at least 77 cases diagnosed (Meselson et al. 1994). In 2002, 22 cases of anthrax (11 inhalational, 11 cutaneous) were identified as a result of bioterrorism; envelopes containing *Bacillus anthracis* spores were mailed to news media companies and government officials in the USA (Jernigan et al. 2002). No naturally occurring cases of inhalation anthrax had

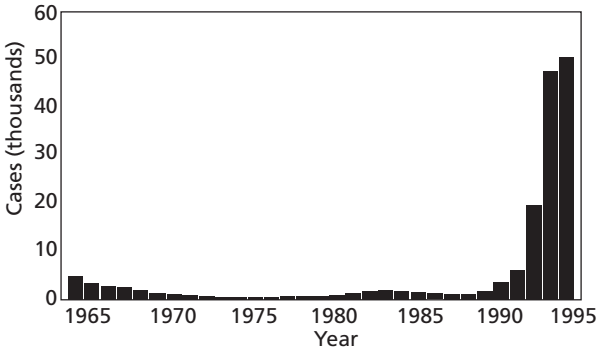

Figure 3 *Reported cases of diphtheria in New Independent States of the Former Soviet Union, 1965–1995. Redrawn from www.cdc.gov/mmwr/preview/mmwrhtml/00043378.htm, with permission.*

been diagnosed in the previous 25 years in the USA. In addition, Salmonella and Shigella have also been used to deliberately contaminate food and cause illness in the USA (Carus 2001; Torok et al. 1997).

INFECTIOUS ORIGINS OF CHRONIC DISEASES

A number of diseases or conditions, previously considered to be noninfectious, have recently been recognized to have an infectious etiology. *Helicobacter pylori* was first isolated from humans in 1982 and is now known to play a central role in the development of diffuse gastritis and duodenal ulceration (Marshall 1989). More than 90 percent of patients with duodenal ulceration are infected with *H. pylori*, and treatment with antimicrobial therapy heals duodenal ulcers; additionally, lower recurrence rates are associated with eradication of *H. pylori*. Presence of *H. pylori*, as determined by serological studies, is also associated with a three- to six-fold higher risk of gastric cancer (Fuchs and Mayer 1995); gastric cancer is the second most common cause of cancer-related deaths in the world. Evidence is still accumulating that *Chlamydia pneumoniae* may have an etiological role in the development of atherosclerosis (Campbell and Kuo 2003).

Guillain–Barré syndrome, a leading cause of acute paralysis, has been associated with infection with *Campylobacter jejuni*; in a study conducted in England and Wales, 26 percent of 96 patients with Guillain–Barré syndrome had evidence of infection with *C. jejuni* (Rees et al. 1995). Peripheral nerves may share epitopes with *C. jejuni*. Other syndromes that are ill-defined and often considered to be immune-mediated may soon also be discovered to have infectious microorganisms playing a central role in etiology, possibly through molecular mimicry (Bolton 1995).

Techniques to identify pathogens that rely on molecular techniques rather than on cultivation have been developed. To identify the bacillus causing Whipple's disease, the bacterial 16S ribosomal RNA sequence from infected tissue was amplified and its phylogenetic relations have been described (Relman et al. 1992; Relman 2002).

SUMMARY

Following the 1992 publication of the US Institute of Medicine report on emerging infections, CDC released a prevention strategy to address emerging infectious disease threats for the USA (CDC 1994a). In 1994, the World Health Organization defined goals to guide implementation of a global effort on emerging infectious diseases (World Health Organization 1994); in 1995, the World Health Assembly passed a resolution calling for attention to the problem of new and re-emerging infections. The original 1992 IOM report was revisited by a new committee in 2003 and its report (IOM 2003) finds that the threat of emerging infections had increased over the past decade. The need to increase global capacity for response, to develop inexpensive and easy diagnostic tests for field use, and to have available the diagnostic reagents, drugs, and vaccines needed has been emphasized, both for naturally occurring diseases and for those diseases likely to result from bioterrorism. As the speed of change in the world continues to accelerate, the challenges confronting us by the re-emergence of old pathogens or the recognition of new ones will likewise be heightened.

INTRODUCTION

Of the infections dealt with in this volume, very many may be acquired in hospital, but these hospital infections have special features. Hospitals bring together uniquely vulnerable hosts and subject them to particular risks of infection from animate and inanimate sources. Apart from being the cause of morbidity and mortality, infection limits the effectiveness and adds greatly to the cost of medical treatment.

The term 'hospital-acquired infection' (syn. nosocomial infection) is applied to any infection causing illness that was not present or in its incubation period when the subject entered hospital or received treatment in an outpatient or accident and emergency department. The increasing blurring between primary and secondary health care systems, and thus often the lack of clarity about the origin of infection, means that the term 'healthcare-associated infection' is preferably used. It includes not only incidents in which a single microorganism spreads from person to person ('cross-infection') or from a common source in the hospital, but also single and apparently unconnected infections. Sporadic and endemic hospital-acquired infections may be less striking than epidemic ('outbreaks'), but they predominate numerically and their control or reduction present the greater challenge.

Some healthcare-associated infections do not differ from infections with the same microorganism in the general population, but many are profoundly affected by the patient's underlying illnesses or by medical or surgical treatments to which they are subjected while in hospital. The source of the infecting organism may be exogenous, from another patient or a member of the hospital staff, or from the inanimate environment in the hospital; or it may be endogenous, from the patient's own flora, which at the time of infection may include organisms brought into hospital at admission and others acquired subsequently. In either case, the infecting organisms may spontaneously invade the tissues of the patient or be introduced into them by surgical operation, instrumental manipulation, or nursing procedure. The concentration of patients with particular illnesses and undergoing similar treatments in specialist hospital units often creates unique niches for hospital pathogens. Healthcare-associated infection may also affect discharged inpatients, outpatients, and staff, and an episode of hospital infection may be initiated by the admission of an infected patient from the general population. Hospital infection may spill over into the community, necessitating investigation and control in both populations. In all considerations of healthcare-associated infection, the source, the mode of infection, and host susceptibility must all be kept in mind. It is clear from a review of the current literature base that

much modern day infection control practice is unfortunately not evidence based. A step forward in this respect is the production of true evidence-based infection control guidelines, such as The epic project (developing national evidence-based guidelines for preventing healthcare-associated infections) (Pratt et al. 2001).

OCCURRENCE, CONSEQUENCES, AND COST OF HEALTHCARE-ASSOCIATED INFECTION

Information about the extent of hospital infection in general may be obtained from incidence or prevalence studies (see Epidemiology of infectious diseases). The relationship between the results of these two types of survey is complex (Freeman and Hutchison 1980). Most investigations are limited to particular sites of infection, such as surgical wounds, or to individual hospital services, such as intensive care. However, in the USA it has been estimated that more than 2 million, and perhaps as many as 4 million, patients are infected in hospital each year. Study of a random sample of patients from 6 449 acute care hospitals gave an incidence of 5.7 infections per 100 admissions (Haley et al. 1985a, b). Ongoing nationwide surveillance of nosocomial infection in the USA is reported in terms of specific infection sites (National Nosocomial Infections Surveillance (NNIS) System 1995). Recent trends have been an increase in bloodstream infections and pneumonias, and an increase in the rate of infections per 1 000 patient-days because of shorter periods of hospitalization (Weinstein 1998). A large proportion of surgical site infections in particular, present in the community even though they were acquired in hospital. This percentage is likely to increase as hospital stays decrease, and therefore, unless an effective form of post-discharge surveillance is carried out then there will be marked under-ascertainment of some hospital-acquired infections (Weigelt et al. 1992; Mangram et al. 1999).

In Great Britain and Ireland, a cross-sectional prevalence survey (Emmerson et al. 1996) suggested an overall nosocomial infection prevalence rate of 9.0 percent, with significantly higher prevalence in teaching (11.2 percent) than in nonteaching (8.4 percent) hospitals. A previous survey (Meers et al. 1981) found a similar overall prevalence (9.2 percent), but Emmerson et al. (1996) point out differences in the study methods and medical practice in the two periods. For example, earlier patient discharge in the more recent survey implied that many surgical wound infections would be detected after discharge from hospital and were therefore not included (Bailey et al. 1992; Weigelt et al. 1992; Byrne et al. 1994; Emmerson 1995). Nationwide prevalence surveys in Spain (EPINE 1992, 1995) have shown an overall nosocomial infection rate of 8.5 percent in 1990, falling to 7.2 percent in 1994. A similar investigation in Norway found a prevalence of 6.3 percent, which was a fall in comparison with previous years (Aavitsland et al. 1992). A prevalence survey in Hong Kong (Kam and Mak 1993) found 8.6 percent of patients to have a hospital-acquired infection. Caution is needed when comparing these and similar figures, as there may be differences in the spectrum of patients, in medical practice, and in definitions of infection. Indeed, there were important differences between the individual hospitals in all these investigations. A similar body site distribution of infections was seen in the studies, with four sites predominating: urinary tract, respiratory tract, surgical wound, and skin (Figure 1). Improvements in prevalence figures are often due mainly to control of urinary tract infection.

A prevalence of hospital infection between 6 and 9 percent has frequently been observed in recent years and it has been questioned whether the 'irreducible minimum' of hospital-acquired infections has been reached (Ayliffe 1986). This stability may indicate some success, in that an increase in the infection rate might have been expected because modern methods of treatment create more opportunities for infection and highly susceptible patients are surviving in greater numbers. Nevertheless, an examination of many aspects of current hospital practice suggests that the incidence of infection could be reduced.

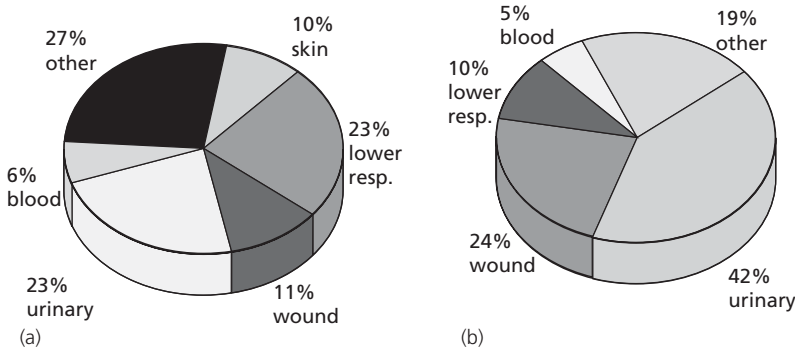

Figure 1 *Occurrence of hospital-acquired infection by site:* **(a)** *UK, prevalence survey (Emmerson et al. 1996);* **(b)** *USA, incidence survey (Haley et al. 1985b)*

Most types of hospital infection cause appreciable morbidity and may lead to residual disability and even death, although a significant worsening of outcome may be difficult to demonstrate statistically except in very large samples of patients (Freeman et al. 1979). Some impression of the impact of hospital infection can be gained from the large prevalence and incidence studies, as can an estimate of the increased cost of care. Martone et al. (1992) suggested that, in the USA, a hospital-acquired infection results in an average of 4.0 extra days of stay. The average extra charges (1992) were $2 100, giving an estimated annual national cost of more than $4.5 billion. It was estimated that more than 19 000 deaths were due directly to hospital infection and that this was contributory to a further 58 000 deaths. Similar figures are not available in Europe. In a 1988 case–control study in England it was established that hospital infection in surgical patients added an average of 8.2 days to hospital stay with added costs of £1 041 (Coello et al. 1993). Antibiotic resistance in the infecting organism adds to costs and reduces the effectiveness of treatment (Holmberg et al. 1987). A socio-economic study of hospital-acquired infection in the National Health Service (NHS) in England in 1994/1995 used modeling based on logistic regression to calculate confidence limits for the estimated increased lengths of stay (Plowman et al. 2001). Extrapolating from measurements in one district general hospital, the calculated annual cost to the NHS was £1 000 million (Plowman et al. 2001). The study examined approximately 4 000 inpatients and identified 7.8 percent as having acquired at least one hospital-acquired infection. Additionally, 30 percent of this hospital-acquired infection cohort, and 19 percent of the remainder reported post-discharge symptoms consistent with the diagnosis of urinary tract, chest, or surgical infections. On average, a patient with hospital-acquired infection spent 2.5 times longer in hospital, and cost £3 000 more to treat than a similar nonhospital-acquired infection patient. This sum is of a similar order of magnitude to other studies, and highlights both the socioeconomic burden of hospital-acquired infections and the potential for savings and/or health gains if even only a small proportion of these can be prevented. Indeed, the control of hospital-acquired infection has been characterized as one of the most cost-effective of health care interventions (Haley et al. 1985b; Chaudhuri 1993; Wenzel 1995).

HISTORY OF KNOWLEDGE OF HEALTHCARE-ASSOCIATED INFECTION

A chapter devoted to hospital-acquired infection appeared for the first time in the seventh edition of this book, reflecting the growth of interest in hospital epidemiology and infection control, but the subject is not new. The need to isolate patients with obviously infectious diseases has been recognized since ancient times and the spread of infection that might ensue from the introduction of such patients into hospitals has been known for centuries. However, segregation of fever hospitals from general hospitals dates only from the early nineteenth century and the usefulness of this measure was not demonstrated statistically until much later. Hospital-acquired infection and the consequent mortality probably reached their peak in the nineteenth century. The following brief account includes only the salient references, but the more recent papers referred to (e.g. Cruickshank 1944; Williams 1956; Ayliffe and English 2003) supply more detail.

The nineteenth century

Urban overpopulation and hospital overcrowding made hospitals places of dread for the poor. There was uncontrolled puerperal sepsis, and surgical sepsis caused death in most cases of compound fracture admitted to hospital. Crossinfection in children's hospitals was associated with mortality rates of 25–40 percent. The now well known work of Semmelweiss (1861) on puerperal sepsis was largely disregarded at the time. He observed its association with medical staff and students who attended patients and also performed autopsies. Semmelweiss deduced that the disease was spread by 'morbid matter' on their hands derived from cadavers or other affected patients. A dramatic reduction in infection rates was achieved by the introduction of hand-washing with chlorinated lime.

At the same time, and to greater immediate effect, Florence Nightingale, after her experience of hospital sepsis at Scutari and her reform of the army medical services, turned her attention to British hospitals. In a much quoted remark in her book *Notes on hospitals* (Nightingale 1863) she states:

> It may seem a strange principle to enunciate as the very first requirement in a Hospital that it should do the sick no harm . . . the actual mortality in hospitals, especially in those of large crowded cities, is very much higher than any calculation founded on the mortality of the same class of diseases among patients treated *out of* hospital . . .

Florence Nightingale established important principles of nursing, hospital design, and hygiene, while remaining sceptical of the germ theory of disease. Further evidence was provided by the survey of the sequelae of amputation by Simpson (1869) which established that sepsis, gangrene, and pyemia were very much more common in large urban hospitals than in rural practice.

At about this time Lister (1867a, b) introduced his 'antiseptic surgery', with extensive use of carbolic acid to pack wounds, especially of compound fractures, to sterilize instruments and sutures, to decontaminate his

hands, as well as use as an air spray. He observed a considerable improvement in the results of treatment of compound fractures and of surgical operations. Lister came to appreciate that the air spray did not add greatly to the effectiveness of the other measures, and that what he was introducing was a barrier between the patients' tissues and infection. 'Antiseptic surgery' was later replaced by von Bergman's 'asepsis' (Schimmelbusch 1894) and by the end of the century, with the introduction of surgical gloves in the USA (see Halsted 1913), the measures in use in a modern operating theater had to a large extent been introduced.

During these years, when many fundamental discoveries in bacteriology were being made, other principles of hospital infection control were established. Flügge (1897, 1899) showed the importance of droplet and aerial spread of tuberculosis and, with Hutinel (1894) and others, established basic isolation systems for diphtheria and other infectious diseases in children's and fever hospitals.

The early twentieth century

The discovery of pathogenic bacteria provided a new basis for the study of hospital infection, and the importance of *Streptococcus pyogenes* was demonstrated during this period, in burn (Cruickshank 1935) and postoperative (Okell and Elliott 1936) infections. Cubicle and barrier nursing was introduced widely (Crookshank 1910) and was shown to be effective in preventing the spread of childhood fevers, except chicken pox and measles.

Aseptic surgery was for a time deemed adequate to keep wound infection to a low level, but this complacency was shattered by the experience of two world wars, when large open wounds readily became infected in the base hospitals (Cruickshank 1944). The local application of mild antiseptics to the wounds proved ineffective (Cruickshank 1944; Williams 1956). The arrival of penicillin in the later years of the Second World War gave considerable benefit (Fraser 1984).

Though Dukes (1929) recognized the importance of the indwelling catheter as a means of introducing infection into the bladder, this was forgotten. The idea was revived much later with the introduction of closed drainage systems (Gillespie 1956; Kunin and McCormack 1966).

The antibiotic era

The introduction of penicillin banished from hospitals the terrible cases of chronic sepsis, mainly caused by *Staphylococcus aureus* (Fletcher 1984). Nevertheless, the era of antibiotics ushered in for the first time a period in which staphylococcal, rather than streptococcal, infection dominated the scene (Williams 1956). Penicillin-resistant, and later multiply-resistant, *S. aureus* strains (Clarke et al. 1952) which had additional properties of transmissibility and virulence, caused serious wound, burn, and other sepsis. Interest in air-borne and dust-borne spread, as well as transmission on the hands of attendants, revived. From this period date many of the established methods of infection control: the supply of clean air for operating theaters, procedures for wound dressings, and the provision of isolation units, for example (Williams et al. 1960). So does the present general system for hospital-infection control: the appointment in the UK of medical control of infection officers (hospital epidemiologists), infection control nurses (nurse practitioners), and control of infection committees (Colebrook 1955, Subcommittee of the Central Health Services Council 1959; Gardner et al. 1962). Similar arrangements were established in the USA, where the first nurse practitioner in the discipline was appointed in 1963 (Osterman 1981).

Antibiotic treatment and hospital infection control are intimately entwined. The use of antibiotics, although not the only influence, has altered the prevailing pathogens in hospital infection. *S. pyogenes* was almost banished and, later, resistant gram-negative bacilli replaced *S. aureus*. Then gram-positive bacteria, *S. aureus*, coagulase-negative staphylococci, enterococci, certain corynebacteria, and *Clostridium difficile*, re-emerged. The emergence of resistant gram-negative bacteria, such as *Klebsiella* spp. with extended spectrum β-lactamases, *Stenotrophomonas maltophilia* and *Acinetobacter baumannii*, has occupied much attention recently. Changes in hospital practice may favor particular pathogens irrespective of their susceptibility to antibiotics. An example is the association of coagulase-negative staphylococci of varied antibiotic sensitivity with prostheses and cannulae. The availability of antibiotics has allowed the development of modern medical treatment, for example major surgery and the use of immunosuppression, associated with new infection risks and a new range of pathogens.

Antibiotic resistance may increase the impact of hospital infection that would otherwise be of small importance and may necessitate a change to less satisfactory and more expensive antibiotics. It also appears to worsen the prognosis of infection (Hart 1982; Holmberg et al. 1987; French et al. 1990). On occasion it may exclude the possibility of using antibiotics to remove the source of infection in an outbreak. Hospital infection control measures, such as isolation, are extremely important in preventing the spread of resistant bacteria.

The development of multiple resistance in hospital pathogens, without the prospect of new antibiotics to deal with them, is alarming. There have been reports of infection by strains resistant to all established antibiotics (Murray 1991; Tomasz 1994), accounts of untoward failures of treatment (Armstrong et al. 1995), and trends towards resistance to agents favored for treatment and

prophylaxis, such as the late generation cephalosporins and the fluoroquinolones (Burwen et al. 1994; Jones et al. 1994; Goldstein and Acar 1995). It has been suggested that the end of the antibiotic era may be near, or that the safety of some forms of hospital treatment may be severely compromised (Kunin 1993; Tomasz 1994). Much evidence suggests that particular resistance problems in hospital-acquired infection have resulted from the routine, unthoughtful, or 'blanket' use of antibiotics in courses that are too long. Restraint, enlightened prescribing, and control of antibiotic use in hospitals may prevent a worsening of the problem (Gould 1988; Report 1995; Editorial 1996; Tenover and McGowan 1996). This has been recognized by the medical and scientific community for some years and has also been acknowledged by public bodies. An important landmark was the inquiry into antimicrobial resistance by the House of Lords in the UK. This report called on governments to recognize the threat, educational authorities to move antibiotic resistance up the agenda, and food producers to curb use in animals (Select Committee on Science and Technology 1998).

More recent developments

For a period, the importance of multiply-resistant *S. aureus* appeared to fade (Ayliffe et al. 1979) and interest shifted to gram-negative bacilli: antibiotic-resistant enterobacteria, such as *Klebsiella* and later *Serratia* spp., which caused large outbreaks of colonization, with some clinical infections. Infection by *Pseudomonas aeruginosa* came to prominence with the increasing number of patients rendered susceptible by illness or treatment. The infecting bacteria appeared to be favored by the antibiotics in current use in the hospitals. More recently, possibly as a result of the introduction of new antibiotics, and the extensive use of indwelling medical devices, gram-positive cocci have again become the predominant causes of infection. *S. aureus* strains resistant to even more antibiotics ('methicillin-resistant *S. aureus*', see later under Staphylococcus aureus) have been as difficult to control as those encountered in the 1950s and multiply-resistant strains of *Staphylococcus epidermidis* have been the most common pathogens in some units. *Enterococcus* spp. resistant to all current antibiotics including vancomycin (see later under Enterococcus spp.) have presented problems in specialized units. Outbreaks of diarrhea and colitis caused by *C. difficile* (see section on Clostridium difficile below) have followed the use of broad spectrum antibiotics, such as cephalosporins. The increase in tuberculosis in immunosuppressed patients (see later under Enterobacteriaceae) and the occurrence of multiply-resistant strains have revived the need for isolation facilities and procedures to prevent air-borne spread of infection to patients and staff. On the other hand, the rediscovery of the principles of effective antibiotic prophylaxis in surgery has done much to prevent endogenous wound infection, for example, in colonic surgery.

The spread of viruses from patients admitted to hospital to other already sick patients remains an uncontrolled problem, particularly with respiratory syncytial virus (RSV) and other respiratory viruses in children's hospitals. Spread of viral gastrointestinal infection has been a major problem (see later under Viruses). The larger numbers of immunosuppressed patients has been associated with an increasing incidence and variety of fungal infection (see later under Fungi and protozoa).

Methods of controlling hospital infection established earlier have been questioned. The UK Medical Research Council (Medical Research Council, Subcommittee of the Committee on Hospital Infection 1968) conducted an inquiry into the measures used in operating theaters. In the USA, efforts to establish the cost-effectiveness of infection control measures culminated in the SENIC study (see later under Surveillance) which demonstrated cost savings by the employment of effective numbers of infection control staff and the institution of preventive measures. Methods of surveillance have been further refined and computerization of records has assisted in this process. It has been important to focus the system of surveillance and control of hospital infection on areas of most effective cost benefit. The need to integrate infection control in the hospital with the wider community has been re-emphasized.

Severe acute respiratory syndrome

Following reports in February 2003 of a mystery respiratory illness affecting some 300 people in Guangdong province, mainland China, a new disease entity was described – severe acute respiratory syndrome (SARS). This disease has subsequently been shown to be caused by a novel coronavirus (Ksiazek et al. 2003; Drosten et al. 2003; Peiris et al. 2003). As of 7 August 2003, some 8 422 cases had been notified to the World Health Organization (WHO) of whom 916 had died. The majority of cases occurred in mainland China (5 327 cases, 349 deaths), Hong Kong (1 755 cases, 300 deaths), Taiwan (665 cases, 180 deaths), Singapore (238 cases, 33 deaths) and Canada (251 cases 41 deaths) (Lee et al. 2003; Tsang et al. 2003; Poutanen et al., 2003; Booth et al. 2003; Ho et al. 2003). The deaths were age-stratified: age <24, <1 percent mortality; 25–44, 6 percent mortality, 45–64, 15 percent mortality; >65, 50 percent mortality. Underlying diseases, such as diabetes, were important cofactors in morbidity and mortality. Spread is thought to be predominantly by large droplets and therefore close contacts are most at risk. The possibility of fecal–oral transmission is still debated and for how long patients are infectious remains unknown. It is possible that some patients become 'super spreaders' and are

more infectious than others. There is not much evidence concerning the role of fomites, though studies have shown that the virus can remain viable for over 24 h on inanimate surfaces. Survival in feces may be as long as 96 h, but the relevance of this fact is unknown.

Meticulous attention to infection control procedures were shown to be most effective in preventing the spread of SARS within a healthcare setting (Ho et al. 2003; Seto et al. 2003; Wenzel and Edmond 2003). Ideally, SARS patients should be nursed in an isolation room with negative pressure relative to the surrounding area or a single room with own bathroom and toilet facilities. The personal protective equipment for all healthcare workers includes for routine use, an N95 EN 149:2001 approved respirator/mask or equivalent (95 percent filter efficiency against particles 1 micron in size or smaller, a tight facial seal – less than 1 percent leak); an FFP2 mask with minimum filter efficiency of 92 percent is deemed equivalent. Masks should be fit tested according to the manufacturer's recommendations and fit checked each time the mask is put on. (To check test the mask, the wearer takes a quick, forceful inspiration to determine if the mask seals tightly to the face.) For high risk procedures which generate aerosols and require prolonged very close contact with affected patients (e.g. intubation prior to ventilation, taking respiratory samples, suctioning whilst the patient is being ventilated), a P-100 half face respirator mask (FFP3 is deemed equivalent, minimum filter efficiency, 98 percent). Eye protection (goggles or face shield) when providing direct patient care during cough producing and aerosol generating procedures, and where there is potential for spattering or spraying of body substances. Droplet and contact precautions (including use of gowns and gloves). Instructions are given for removing and discarding masks to avoid transmission of virus during this process. Hand hygiene is also emphasized. More stringent infection control recommendations may be required in specific situations, e.g. outbreak management in a healthcare facility.

MODE OF SPREAD OF INFECTION IN HOSPITALS

Air-borne spread

With the tradition of the spread of disease by effluvium or miasma, it is not surprising that air-borne spread of infection, for example of tuberculosis, was demonstrated early in the scientific era of bacteriology (Flügge 1897, 1899). Interest in this route went into eclipse in the early years of this century (see Williams 1956) to be revived in the later 1930s and the 1940s. The contribution of the air-borne route to common hospital infection remains the subject of controversy. Clearly, the effectiveness of this route depends on the source, on the number of microorganisms present, and the degree of dispersal, whether in droplets, in droplet nuclei or on skin scales; on survival and retention of pathogenicity by the microorganisms in the air or environment (or their death, impairment, or dilution there); on the size of the infecting dose; and on the local or general susceptibility of the persons exposed to infection. Air-borne spread of infection has been reviewed in detail by Ayliffe and Lowbury (1982) (Airborne bacteria).

Bacteria can be counted in air by the slit sampler, which draws in air and impacts the particles on to a moving culture plate. Settle plates, which are agar plates exposed on horizontal surfaces for measured periods of time, capture a limited range of the particles from the air and are not quantitative. Small hand-held samplers (e.g. centrifugal samplers) are now available. They are easier and less disturbing to use in a busy operating theater than the slit sampler, and are adapted to making counts during operations and in different areas near the operation itself. Some, however, extract only some of the particles and give results that are not as accurate as, or comparable with, those obtained with the slit sampler (Whyte 1981). Outside the operating theater, the provision of good quality air for severely neutropenic patients in the absence of high efficiency particulate air (HEPA) filters, especially in the context of preventing aspergillus infection, is the other major indication for occasional air sampling. The absence of agreed standards, however, makes interpretation of air sampling outside the operating theater difficult (Humphreys 1993).

TUBERCULOSIS

Clinical experience and experiments with guinea pigs indicate that air-borne spread of tuberculosis can occur by the transfer of very few microorganisms. Patients differ greatly in their ability to transmit tuberculosis (Riley et al. 1962) and the susceptibility of the recipient is also very significant. Only patients with smear-positive pulmonary tuberculosis are regarded as constituting an infection risk and requiring single room isolation. Infectivity declines rapidly after effective treatment is initiated so that only 2 weeks of isolation during treatment is recommended (but see later under *Mycobacterium* spp.). Multidrug-resistant (MDR) tuberculosis in HIV patients during recent years has been associated with nosocomial spread to patients and healthcare workers and emphasizes the need for early identification of positive patients and patient isolation (Beck-Sagué et al. 1992).

PNEUMOCOCCAL INFECTION

Much infection by *Streptococcus pneumoniae* is endogenous and it has not been customary to isolate patients with pneumococcal pneumonia. The appearance of penicillin-resistant and multi-resistant strains has been associated with significant mortality (Pallares et al. 1995). The ready transmission of these emerging organisms has

demonstrated the need to contain such infections (Gould et al. 1987), but clusters of cases also occur with some more sensitive strains, which appear to have the ability to cause lobar pneumonia in the relatively healthy (Davies et al. 1984). When the disease has been convincingly diagnosed by a Gram stain of sputum, it may therefore be advisable to isolate patients with pneumococcal pneumonia for the first 24 h of treatment. Protection of vulnerable patients with the currently available polyvalent vaccine becomes more important as resistance increases (Austrian 1994).

MENINGOCOCCAL INFECTION

Meningococcal infection acquired in hospital is uncommon, but isolation for the first 48 h of treatment is advised. Among staff, only those who have had particularly close contact with the patient, as in mouth-to-mouth resuscitation, need be offered prophylactic antibiotics.

OTHER BACTERIAL INFECTIONS

The evidence for spread by air of *S. aureus* and *S. pyogenes* is contradictory. These bacteria are carried by many normal people (Williams et al. 1960); streptococci are readily shed from the upper respiratory tract, by coughing, sneezing, and singing (Lidwell 1974), as are staphylococci on skin squames during physical activity. There is considerable variation in the degree of shedding. *S. aureus* is carried particularly in the perineum and nares and males tend to shed more staphylococci than females. Infected lesions on patients provide rich sources of these bacteria and release into the air is brought about by movement of secondarily contaminated articles, such as bedclothes, protective clothing, bed curtains, dressings, and dust. The numbers in the air can be reduced by disinfection with ultraviolet light or chemicals, by such simple measures as damp, rather than dry, dusting or cleaning, and by control of air circulating between infected and susceptible persons. These measures are not, however, always effective in reducing infection rates. Striking results are most common when the prevailing infection rate is very high, as where dressings are handled, or where there is a large exposure of undefended tissue, as in burns. The important experiments in burned patients by Lowbury et al. (1970) suggested that infection by gram-negative bacilli, e.g. *P. aeruginosa*, was almost entirely by contact, infection by *S. pyogenes* by air and staphylococcal infection by both routes. Measures to control ventilation have on occasion resulted in a decline in the rate of nasal acquisition of organisms by patients. Several workers have found it impossible to control the spread of resistant strains of staphylococci by contact barriers alone, but have achieved success with the use of a separate isolation unit or decontamination of the environment (Pearman et al. 1985). It may be that for these strains the selection pressure of antibiotics administered to the recipient is of importance in allowing colonization from very small inocula. These are situations in which air control is likely to yield good results.

Gram-negative bacilli tend to die when desiccated and infection by the aerial route is confined mainly to spread by nebulized spray.

VIRAL INFECTION

Smallpox was notorious as being readily transmitted by very few infective particles by the air-borne route. The most common viral infections transmitted by air in hospital are chicken pox, measles, influenza, and respiratory syncitial virus (RSV). Availability of immunofluorescence techniques for the rapid diagnosis of RSV renders isolation or 'cohort nursing' (placing patients with similar infections in the same ward or area) shortly after admission to hospital is an increasing possibility and it is recommended (Editorial 1992). It seems that transmission of other childhood exanthems requires closer contact. Small round structured viruses (SRSV) (now referred to as noroviruses) are an increasing cause of nosocomial diarrhea and vomiting. Large inocula are present in vomitus and the air-borne inhalation route as well as the fecal route is now recognized as an important means of transmission (Caul 1994).

FUNGAL INFECTION

Dispersal by spores is a feature of most filamentous fungi, but only *Aspergillus* spp. have been shown to be a significant cause of air-borne infection. This may occur after cardiac surgery or in immunosuppressed patients. Outbreaks have been associated with building work in hospitals (Opal et al. 1986) or inexpert filter changing in operating theater ventilation systems. Other fungi occasionally cause clusters of infections by aerial spread, e.g. phycomycetes (del Palacio Hernanz et al. 1983). Exceptionally, other fungi that cause cardiac valve infection are thought to have arrived via air. Effectively filtered air should be supplied to certain classes of susceptible patients (Rhame et al. 1984). *Cryptococcus neoformans* is frequently found in pigeon droppings around hospitals, but there is no convincing evidence of air-borne spread from this source to susceptible patients.

INFECTION IN THE OPERATING THEATER

The pathogenesis of postoperative infection is complex, but most infections arise from the patient's own flora and the remainder are acquired mainly from staff in the operating theater (Ayliffe 1991). At one time 'aseptic surgery' appeared to offer all that was needed to minimize postoperative infection. In the 1940s, partly stimulated by cases of clostridial infection thought to be due to dust, interest was revived in the possibility that improved ventilation of operating theaters and other measures designed to limit air-borne infection would

reduce it further. This was reflected in the principles of modern systems of operating theater ventilation and the design of modern operating areas, including plenum ventilation to ensure flow of air from the theater to the outside rather than the reverse (Humphreys 1993). Satisfactory operating theater clothing, small operating teams with the minimum of movement and restriction of the patient's blankets and dressings to anterooms are other important factors in minimizing postoperative infection, because all these measures reduce the air levels of bacteria in the theater (Dharan and Pittet 2002). Even so, any human activity raises the levels in a conventionally ventilated theater, but these bursts should be quickly suppressed by effective ventilation. Recent publications have addressed the problems of behavior and rituals in operating theaters (Woodhead et al. 2002) and the microbiological commissioning and monitoring of operating theater suites (Hoffman et al. 2002).

The bacteria found in the air of a properly ventilated operating theater are rarely pathogens in the usual sense. For example, they rarely include *S. aureus* or *S. pyogenes*. Indeed, it is difficult to find proof that reducing microorganisms in the air by conventional ventilation systems is beneficial in preventing surgical wound infection, although there have been instances in which the introduction of the systems described above have apparently resulted in a fall from an undesirably high incidence of wound infection (Blowers et al. 1955; Shooter et al. 1956).

It was an early suggestion that in surgical operations on healthy tissues with good defenses, a small degree of contamination with air-borne bacteria is unlikely to result in infection, but that less healthy tissues and areas such as the meninges may not be able to deal with such contamination (Cairns 1939). In the very specialized field of orthopedic surgery, the incidence of infection has fallen with increased expertise, and it is now clear that the spectrum of infecting agents includes *S. epidermidis* and propionibacteria, such as are found in significant numbers in the air of a conventional operating theater. Charnley and Eftekhar (1969) and others found very low rates of clinical infection when ultraclean air was provided, but increased operative skill and the prophylactic use of antibiotics may have played a part in this. A multicenter trial (Lidwell et al. 1982) compared conventional theater conditions, provision of ultraclean air, exhaust-ventilated clothing and, incidentally, use of prophylactic antibiotics, in 8 055 operations (6 781 hip replacements; 1 274 knee replacements). The results (Figure 2) showed a cumulative benefit for the three measures and indicated that antibiotic prophylaxis alone would achieve more than the expensive provision of ultraclean air alone. A close relation was found between the levels of bacteria in the air and the risk of infection, and between staphylococci isolated in infected joints and those found in the patient or operating team at the time of operation. The benefit of very low levels of air-borne bacteria has not yet been proven for other types of surgery, but it would probably apply to the insertion of other prostheses, such as artificial heart valves and cerebrospinal fluid shunts.

Infection associated with water

LEGIONNAIRES' DISEASE

The Legionellaceae are widespread in water (Legionella), including potable water supplies, and many cases of Legionnaires' disease occur sporadically in the community. In one study in the UK they accounted for 15 percent of pneumonia cases (Macfarlane et al. 1982), but in other studies they were much less common. Hospitals are not spared the occurrence of legionellae in their water supplies (Tobin et al. 1981) and have suffered a series of outbreaks (Bartlett et al. 1986), mainly of infection with *Legionella pneumophila* (particularly serotype 1) but also with *Legionella micdadei*, *Legionella bozemanii*, and *Legionella longbeachae*.

The factors that favor hospital-acquired Legionnaires' disease are as follows. Hospital patients include a number of individuals with an impaired immune system who are more likely to become clinically infected with legionellae and who have a higher mortality than otherwise healthy subjects. Hospital-acquired infection occurs in patients rather than in staff who may nevertheless have circulating antibodies, which suggests exposure. Water in medical equipment that delivers a nebulized spray may become contaminated (Arnow et al. 1982). Hospitals are large buildings with extended hot-water

systems. It has been customary to run these at lower than usual temperatures, for economy and for the safety of patients. Peak demand may lead to a further fall in temperature. Legionellae can tolerate temperatures to 55°C and can grow at 35–45°C and thus are adept at surviving and flourishing in the water systems of buildings (Latham et al. 1992). There have been many examples of the association of cases in hospital with hot-water systems, particularly with those supplying showers (Tobin et al. 1980), or run at a low temperature (Meenhorst et al. 1985). Ancillary systems used only intermittently may discharge water that has stagnated, allowing growth of legionellae in sludge or biofilm, perhaps assisted by substances from plumbing materials (Bartlett et al. 1986). Cases associated with release of stagnant water into the general system have been described (Fisher-Hoch et al. 1982). Hospital ventilation systems often have air-cooling towers in which potentially contaminated water flows over pipes through which air is circulated. Faults in such a system may allow direct access of the water to the air, or drift from the tower may contaminate the air at a later stage. Outbreaks caused by contaminated cooling towers can be explosive, occurring over a short period of time, whereas those due to domestic water systems may be more insidious and may only be revealed after active surveillance.

The source of infection of patients in hospital is thus environmental water; person-to-person spread is unknown. As legionellae are ubiquitous in water systems, regular monitoring is of little value in hospitals that have had no previous problems, but this is more problematical in hospitals where documented cases or outbreaks of nosocomial infection have occurred (Fallon 1994). Prevention depends on the good design, installation, and maintenance of hot-water and ventilation systems and of the use wherever possible of air-cooled condensers rather than water-cooling towers; on keeping domestic hot water at high temperatures (>60°C for storage and >50°C at the point of delivery) unless patients are thereby exposed to risk of scalding, as for example, in mental handicap departments; on flushing those parts of the hot-water system that are subject to stagnation; on chlorination and biocide treatment of water; and on the use of sterile water in nebulizers, etc. A recent outbreak was terminated by a series of measures including the use of copper and silver ions introduced into the water system as disinfectants (Colville et al. 1993). Preventive measures, which should involve clinicians, microbiologists, and engineers, must be accompanied by good surveillance for the occurrence of Legionnaires' disease with adequate diagnostic facilities, and by contingency plans to be brought into action when possible hospital-acquired infections occur. In the UK, the 1995 Approved Code of Practice (ACoP) (L8), The prevention or control of legionellosis (including legionnaires' disease), and the guidance booklet HS(G)70 The control of legionellosis including legionnaire's disease, have both been recently revised and combined into a single document (Health and Safety Executive 2001). In its new form, the document is split into two parts. Part 1 is the ACoP itself, and part 2 of the document then provides guidance specific to particular systems, notably wet cooling systems (systems incorporating cooling towers and evaporative condensers), hot and cold water systems, spa/whirlpool baths, and humidifiers/air washers. In addition, a table in appendix 1 of this document provides a useful list of most other systems known to pose a risk, along with a summary of the main recommended control measures and the frequency of their application. For further information about Legionnaires' disease see Legionella.

OTHER BACTERIA IN WATER AND IN DAMP AREAS IN THE HOSPITAL

Other gram-negative bacteria may be present in hospital water supplies, and their multiplication is encouraged by warmth and the other factors enumerated above. They may then act as opportunist pathogens in hospital patients. *Aeromonas hydrophila*, for example, causes pneumonia and sepsis in immunologically impaired patients and Picard and Goullet (1987) found *A. hydrophila* in maximal numbers in hospital water in hot weather. Risks of infection exist whenever aqueous fluids or damp objects, in or on which gram-negative bacteria have had an opportunity to multiply and have not subsequently been destroyed, come into intimate contact with susceptible patients. Examples include dental water-cooling systems, cooling cycles in autoclaves, pressure-monitoring systems on arterial lines, unsterilized lotions, and irrigation solutions.

Pseudomonas spp. are to be found in mains water supplies and may multiply in any moist area. They have simple growth requirements and often show considerable resistance to antibiotics and may even survive in disinfectants, such as those prepared for multiple use. *P. aeruginosa* is ubiquitous in wet hospital sites. It has been found in food and water, ice machines (also implicated recently with infections due to *Stenotrophomonas maltophilia* in neutropenic patients in the UK), pharmacy preparations, plaster of Paris, mouthwash, dental water units, nebulizers, whirlpools and other hot baths, mattresses, sinks, taps, potted plants, flowers, flower vases, and so on. In some instances, particularly when the organisms have been introduced into the gastrointestinal or respiratory tract or the patients were particularly susceptible, colonization and later infection have been shown to have arisen from such sources. In other instances, however, the strains carried by the patients were different from those found only at inanimate sites in the wards. The patients' strains contaminated the immediate surroundings of the carrier patients and the hands of members of the staff and were occasionally

transferred to other patients (Levin et al. 1984; Allen et al. 1987). A more recent potential hazard that has been highlighted is pseudomonas infection following birth in water baths.

Burkholderia (Pseudomonas) cepacia, and other bacteria such as *Burkholderia pickettii*, possess the attributes that make them suitable for the role of hospital opportunists. Under certain conditions *B. cepacia* grows in distilled water and in the presence of aqueous chlorhexidine and quaternary ammonium compounds and may cause infections in neonates (Kahyaoglu et al. 1995). It has frequently been isolated from badly formulated, unsterilized supplies of these antiseptics, and even from povidone-iodine. Infection from a contaminated disinfectant or other fluid is generally associated with application to an open wound (Bassett et al. 1970), intravenous injection (Phillips et al. 1971), or urethral catheterization (Speller et al. 1971). *B. cepacia* is increasingly recognized as an important pathogen in patients with cystic fibrosis. In this group of patients the most important source is respiratory secretions with subsequent patient-to-patient spread. There is increasing evidence that some genomovars of *B. cepacia* complex are more virulent than others (e.g. genomovar III), and consequently patient segregation may be advisable (Govan et al. 1996; Mahenthiralingam et al. 2002).

Infection acquired from food

As in the general population, gastrointestinal pathogens may be transmitted by foods served to patients. Hospital food can also be a source of antibiotic-resistant bacteria, which may colonize the gut and later cause infection in susceptible patients. Of 1 280 outbreaks of infectious intestinal disease reported to the Communicable Disease Surveillance Centre in England during the period 1992–94 (Djuretic et al. 1996), 189 occurred. Salmonella infections were particularly associated with poultry or eggs, and *Clostridium perfringens* infections with meat. Outbreaks of salmonella infection in hospitals are important because they may cause serious effects in the very young, the elderly, and in patients with impaired immunity (Taylor et al. 1982) and may disrupt the working of the hospital (Kumarasinghe et al. 1982). The catering faults most often responsible are failures of catering staff to follow good practice: incomplete defrosting of frozen meats and poultry, insufficient cooking of large amounts of food, use of raw or insufficiently cooked egg products, inadequate chilling and storage, and contact between food to be consumed without further cooking and raw poultry. Effective processing of all foods, including poultry and eggs, and safe preparation, storage and distribution of food, are important in hospitals, where particularly susceptible patients are exposed to risk (Wilkinson 1988). The system of centralized preparation of food that is immediately chilled to safe storage temperatures and later regenerated in a standard system after distribution ('cook-chill' or variations on this theme) allows, and demands, careful control and monitoring of bacterial content (Wilkinson 1988; Wilkinson et al. 1991; Shanaghy et al. 1993).

Most outbreaks of salmonellosis in hospital are not food-borne, but are caused by person-to-person spread or contaminated fomites. In the 3-year survey by Djuretic et al. (1996), only 19 of 189 hospital episodes were mainly food-borne, whereas 156 were mainly person to person; in seven, both routes were equally involved and in seven the mode of spread was unknown. Similar figures have been reported in the USA (Baine et al. 1973). In a prospective investigation during a period of 2 years, food-borne spread probably accounted for only 11 percent of hospital outbreaks, although these tended to be the larger incidents (Palmer and Rowe 1983). Careful epidemiological investigation is required to determine the mode of spread and to define the population for further study (Palmer and Rowe 1983). There was a recent report by a London hospital of an outbreak of *Salmonella* Enteritidis phage type (PT) 6a. There were 27 hospital-acquired cases over 1 month in 2002. The source was thought to be imported raw shell eggs. A second cluster of approximately 25 hospital-acquired cases predominantly due to S. Enteritidis PT 1 occurred within the following month. During the outbreaks there were six deaths among patients identified as having salmonella, although none of these was directly attributable to salmonella infection (Public Health Laboratory Service 2002).

Hospital food is well known to often be a source of antibiotic-resistant gram-negative bacilli that colonize patients: *P. aeruginosa*, *Escherichia coli*, *Klebsiella* spp., and others (Shooter et al. 1969; Cooke et al. 1970, 1980; Casewell and Phillips 1978). It is possible for dietary components, equipment, and preparation areas to become contaminated with nosocomial bacteria, particularly in facilities for the preparation of individualized diets, including enteral feeds (Casewell 1982). Colonization of the bowel is an important source of infection of other sites, for example of bacteremia in granulocytopenic patients, who may benefit from a diet of low microbial content, with avoidance of foods likely to contain pathogenic or antibiotic-resistant bacteria (Schimpff 1993).

Infection by contact

FROM STAFF

Microorganisms on the hands of staff may be resident (persistent over time and not readily removed by hand-washing) or transient (recently acquired from another source). It is generally accepted that the hands of staff are an important vehicle and that hand-washing makes a significant contribution to the control of hospital-

acquired infection (Reybrouck 1983; Larson 1988). The relevant microorganisms can readily be demonstrated on the hands of staff and may easily be transferred to the skin of others by brief contact (Marples and Towers 1979). Introduction of hand-washing has been accompanied by reduction of the infection rate in many studies, from that of Semmelweiss (1861) to more recent investigations of infection by gram-negative bacilli, e.g. Casewell and Phillips (1977). The literature of more than 100 years was reviewed by Larson (1988), who concluded that the evidence strongly supported a causal connection between hand-washing and control. The effect has been observed in a variety of settings under many different hygienic circumstances (Larson 1988).

The most important microorganisms spread by hand contact are *S. aureus* and gram-negative bacilli, such as *Klebsiella* and *Serratia* spp. Carriage on the hands has been suggested as important in the transmission of antibiotic-resistant enterococci (Rhinehart et al. 1990) and of *C. difficile* (Kim et al. 1981; McFarland et al. 1989), but this has not been a consistent finding. In addition, the route has been described for many other hospital-spread pathogens, including *Candida albicans* (Burnie 1986) and even respiratory pathogens: *Corynebacterium diphtheriae* (in the past) and viruses, such as RSV and rhinoviruses (Pancic et al. 1980). With *S. aureus*, attention has been focused on long-term carriage (Williams et al. 1960); gram-negative bacilli also have been demonstrated to persist for long periods on the hands of some persons (Casewell and Phillips 1977; Adams and Marrie 1982). Transient carriage resulting from recent contact with an infected or colonized patient may often be more important. Casewell and Desai (1983) demonstrated that strains of gram-negative bacilli, particularly of *Klebsiella* and *Serratia*, that had caused outbreaks in which infection was apparently spread by staff from patient to patient, survived longer on the hands of volunteers than did strains capable of causing outbreaks only from a point source in food or the environment. The ability of glycopeptide-resistant enterococci to survive for 1 h on fingers has also been shown (Noskin et al. 1995b).

It should be noted that healthcare workers sometimes erroneously wear gloves as a substitute for hand hygiene. Also, hand hygiene products may degrade gloves, and healthcare workers need to be aware of the need to clean hands after glove removal, because of the inevitable contamination that occurs during degloving. The preparations available for hand decontamination and the methods for assessing them have been reviewed (Ayliffe 1980; Reybrouck 1986). Hand hygiene may be designed for the removal of transient flora (Price 1938), which may be achieved by a simple wash with soap or detergent, or even better by an aqueous preparation of an antiseptic with a detergent. Sometimes a residual disinfectant action is needed, with or without reduction of the resident flora, as in the preoperative preparation of a surgeon's hands, or in high-dependency units in the hospital. Iodophors, the bisguanide chlorhexidine, and trichlorohydroxyphenol and related compounds may all be used and all have some residual activity (Ayliffe 1980). Alcoholic preparations, or alcohols alone, are more rapid in action than aqueous preparations and are more effective (Lowbury et al. 1974). Their drying action on the skin can be prevented by the addition of glycerol or other emollients. Alcohol-based hand rubs are quicker to use and aid compliance with hand hygiene policies, but they are unsuitable for use on soiled hands. A minimum of skin flora cannot be reduced further by these processes (Lilly et al. 1979). Methods should be adopted that are suitable for the particular purpose and that avoid damage to the skin and development of resistant flora on repeated use (Ayliffe 1980; Reybrouck 1986). One clinical trial (Doebbeling et al. 1992) compared different hand-washing methods in consecutive periods in intensive care units. A reduction in nosocomial infection was directly demonstrated when chlorhexidine (rather than soap or alcohol) was used; the effect may have been partly due to better compliance by staff. Poor compliance with the prescribed measures is frequently observed and may vary with the professional group, the hand-washing system prescribed, and its ready availability (Albert and Condie 1981; Doebbeling et al. 1992; Gould 1994; Wurtz et al. 1994; Pittet et al. 1999). Importantly, it has been shown that as the intensity of required patient care increases, the compliance with hand hygiene falls (Pittet et al. 1999). Hand cleaning should be carried out immediately before and after each contact with patient of their close surroundings. Efforts are increasingly focused on how to improve healthcare workers' compliance with hand hygiene. Pittet and colleagues recently examined >20 000 opportunities for hand hygiene and successfully improved compliance by healthcare workers from 48 percent in 1994 to 66 percent in 1997 ($p < 0.001$) (Pittet et al. 2000). This was attributed primarily to the promotion of bedside antiseptic handrubs. Hand hygiene improved significantly among nurses and nursing assistants, but remained poor among doctors. Importantly, the sustained improvement in compliance with hand hygiene coincided with a reduction of nosocomial infections and MRSA transmission.

The clothing of personnel can be shown to become contaminated with potential pathogens, such as *S. aureus* and, less frequently, gram-negative bacilli, particularly after the handling of heavily colonized patients (Babb et al. 1983). The significance of this in the spread of infection is unknown.

FROM THE PATIENT'S ENVIRONMENT

The immediate environment readily becomes contaminated with the bacteria carried by a patient. It has sometimes been difficult to prove that organisms from environmental surfaces cause infection (Maki et al. 1982),

partly because the virulence of the bacteria may become impaired. Nevertheless, if heavily contaminated (Sanderson and Rawal 1987), such surfaces must be regarded as a potential source of air-borne organisms and also of infection by direct contact with another patient or via the hands of staff. Whilst it has been known for many years that staphylococci are desiccation resistant and can survive in the environment, thus prolonging outbreaks, emerging pathogens such as *Acinetobacter baumanni* may also persist. In a recent study the mean survival times of sporadic and outbreak strains on glass coverslips were 21–33 days (Jawad et al. 1998). Particularly in the case of bacteria carried in the bowel, which can survive in the environment for long periods, contamination of the environment or equipment may be responsible for the clustering of cases, as with *C. difficile* (Cartmill et al. 1994) and *Enterococcus* spp. (Karanfil et al. 1992). In a review of intensive care unit design and environmental factors in the acquisition of infection, O'Connell and Humphreys (2000), make the point that the inanimate environment of air, water, food, floors, walls, and ceilings can contribute to the risk of acquisition of infection in intensive care patients, although their actual role can be difficult to quantify in most instances. However the design of the intensive care unit (ICU) should be such as to minimize the entry and persistence of microorganisms into this environment and allow the thorough cleaning of any surfaces which may become contaminated (Dieckhaus and Cooper 1998).

Dancer (1999) found that cleaning in the hospital setting is often a neglected component of infection control and many outbreaks occur secondary to suboptimal cleaning. Hospitals provide a reservoir of microorganisms adapted to the hospital environment including the ability to survive harsh environmental conditions. The immediate environment of patients in sometimes heavily contaminated and may include vancomycin-resistant enterococci (VRE), MRSA, *A. baumanii*, *P. aeruginosa*, and *C. difficile*. The hardy spores of *C. difficile*, an organism that can cause serious outbreaks throughout the hospital, can withstand extremes of temperatures and some disinfectants. They also remain viable for a considerable length of time in the environment and are responsible for many outbreaks of infection in general wards and in the ICU (Spencer 1998). Other nonspore-forming microbes, although not as resilient as *C. difficile*, can survive in areas that are damp and poorly cleaned. Standards for environmental cleanliness in hospitals were published in the UK in 1999 with a view to raising the profile of hygiene in hospitals, developing an audit tool and producing prescriptive recommendations from which standards for cleaning in hospitals could be derived (ICNA/ADM 1999). Cleaning and disinfection of the rooms of infected patients are recommended when the patients leave the room or are discharged from hospital. There are ongoing studies as to whether materials with intrinsic antibacterial activity could potentially be used as finishes for walls, floors, etc., and thus help to control environmental contamination (Talon 1999).

Rampling and coworkers (2001) again highlighted the importance of general hospital hygiene in bringing to an end a prolonged outbreak of MRSA. They showed that a dusty ward was an important source of MRSA for their surgical patients. During the last 15 years in the UK, hospital cleaning services have been targeted for cost-cutting in the NHS (Dancer 1999). However, it is difficult to demonstrate that a dusty or soiled environment can actually be hazardous to patients, with little evidence to support this (Ayliffe et al. 1967; Maki et al. 1982; Collins 1988). Nevertheless, a high standard of hygiene should be an absolute requirement in hospitals for aesthetic, as well as clinical reasons. In the long term, cost-cutting on cleaning service is neither cost-effective nor common sense (Blyth et al. 1998; Plowman et al. 1999; Wilcox and Dave 2000). All this emphasizes that basic hospital hygiene, such as cleaning, remains an important element in preventing infection and attempts at cost containment in this area are likely to be counter-productive.

FROM EQUIPMENT

Infection from surgical instruments is now extremely rare, but other items of equipment, even if they do not penetrate the tissue, may convey infection from one patient to another. Some of these escaped attention because the risks associated with them appeared to be low or had not been perceived. Others are pieces of equipment that are difficult to clean and disinfect adequately, or are expensive and in short supply.

Many items that come into contact with patients usually do not need to be supplied sterile, but patients with impaired immunity may be susceptible to opportunist organisms present on or in these. For example, patients with debilitating illnesses may develop superficial and subcutaneous phycomycosis in macerated areas under adhesive plaster contaminated with *Rhizopus* spp. (Gartenberg et al. 1978). Premature babies have become infected by *Rhizopus* spp. from unsterile wooden tongue depressors, used as limb splints (Mitchell et al. 1996).

Bedpans and urinals have been blamed for the spread of enteric bacteria, such as *C. difficile* and antibiotic-resistant gram-negative bacilli (Curie et al. 1978). The bacterial load may be high if the washing process is not efficient, and bedpan washer-disinfectors often do not maintain an adequate temperature for the intended time. The practice of decontaminating urinals in tanks of phenolic disinfectant is often ineffective because of inaccurate dilution of the disinfectant, or its inactivation by organic matter, or by the survival of bacteria in biofilm on surfaces (Curie et al. 1978). Special decontamination measures may be necessary for particularly resistant pathogens, e.g. *C. difficile* and *Cryptosporidium* spp. Rectal thermometers have been believed to be responsible for

the spread of salmonellae (Im et al. 1981) and enterococci (Livornese et al. 1992); all thermometers should be decontaminated after use (Nystrom 1980).

Many fiberoptic endoscopes for gastrointestinal and bronchial use are difficult to disinfect because they do not withstand heating; also their complex channels are difficult to clean. Numerous species have been transmitted by such endoscopes (Spach et al. 1993). Among the most common have been *Salmonella* spp. and *P. aeruginosa* in the gastrointestinal tract and *Mycobacterium tuberculosis* and other mycobacteria in the respiratory system. Endoscopes are readily contaminated with *Helicobacter pylori* and transmission by endoscopy has been demonstrated (Langenberg et al. 1990). Recent updated guidelines on endoscopy disinfection have increased the disinfection contact times, e.g. from 4 to 10 min for 2 percent gutaraldehyde, to provide a greater margin of safety, and have emphasized the importance of water quality of the final rinse (Report of a Working Party of the British Society of Gastroenterology Endoscopy Committee 1998). In the impaired patient infection of other sites and bacteremia may result (Schimpff 1993); bacteremia is particularly likely to follow biliary endoscopy (Struelens et al. 1993). Hepatitis B has rarely been transmitted on endoscopes although they readily become contaminated with the virus (see Ridgway 1985). Spread of human immunodeficiency virus via endoscopes has not been reported. Such accidents can be avoided by a thorough regimen of cleaning and disinfection with a suitable chemical agent, which may be carried out manually or by special apparatus (Fraser et al. 1993; Bradley and Babb 1995) if sufficient endoscopes can be provided (Anon 1988; Fantry et al. 1995; Babb and Bradley 1995).

The ever expanding use of endoscopic procedures in diagnosis and surgical treatment of patients has reinforced the need for safe and effective methods of cleaning, disinfection, and sterilization of these instruments (Ruddy and Kibbler 2002). Reports on the decontamination of minimally invasive surgical endoscopes and accessories have been published (Ayliffe 2000). As the number of patients undergoing endoscopy has increased, the requirements for the safe use of glutaraldehyde and other potentially irritant or sensitizing instrument disinfectants has led to an increased use of automated washer disinfector systems which provide safe containment of hazardous vapor and can remove toxic residues effectively. These automated systems have been shown to be more effective in removing bacteria than manual methods but they are not without problems, and the following issues need to be recognized:

- Many systems are available on the market. Irrespective of whether or not the system has its own wash cycle prior to disinfection, it is recognized that manual precleaning of endoscopes is essential (Babb and Bradley 1995).
- There is a need to ensure endoscope compatibility with the autodisinfector fittings. Endoscopy staff must follow instructions strictly in order to ensure that all endoscope channels are adequately irrigated with disinfectants. There is a need to ensure endoscopes and washer disinfectors are compatible with the disinfectants used.
- Automated systems require regular and adequate maintenance which is time consuming and expensive. Furthermore, some parts of the decontamination process (e.g. brushing lumens and wiping insertion tubes) cannot be automated and thus manual cleaning is still an essential prerequisite.

The most significant problem which has not been addressed by the increased use of automated systems is that of contaminated rinse water derived from either the internal pipework of the washer disinfector or mains water, as well as intermediate tanks and poorly maintained filters. Recent reports have attempted to address this and give recommendations on possible ways of dealing with this problem (MacKay et al. 2002; Report from a Joint Working Group of the HIS and PHLS 2002).

Infection by inoculation

Since the universal introduction of single-use disposable needles and other devices, and satisfactory procedures for the sterilization of surgical instruments, with a wide safety margin, transmission of infection by this route in the developed world has been infrequent. Few agents can resist the standard sterilization processes. The prions responsible for transmissible spongiform encephalopathies (e.g. Creutzfeldt–Jakob disease (CJD)), previously associated with neurosurgery, are highly resistant to most sterilization procedures and therefore instruments used on patients with these conditions should either be disposed of or subjected to prolonged autoclaving at high temperature (Advisory Committee on Dangerous Pathogens 1994). However, there remain infections (1) transmitted by blood transfusion or tissue donation; (2) resulting from accidental injury from contaminated sharp instruments; (3) from contaminated blood; and (4) from other contaminated infusion fluids.

INFECTION TRANSMITTED BY BLOOD TRANSFUSION AND TISSUE DONATION

Infectious agents may from time to time be transmitted to patients by donors of blood, blood products, or tissue. The risk of transmission of the three most important agents, hepatitis B and C viruses and human immunodeficiency virus (HIV), has been reduced to a low level by a combination of donor selection, screening of donations for antigen or antibody, and heat treatment of blood products, but not before countless cases of 'serum hepatitis' had occurred and a considerable proportion of

hemophilia sufferers received factor VIII infected with HIV (Editorial 1984b). Efforts should also be made to exclude other, less common, blood-transmitted infections such as other forms of hepatitis, including δ agent and possibly hepatitis G in the future, cytomegalovirus, Epstein–Barr virus, parvovirus, HTLV-1, brucellosis, syphilis, salmonellosis, malaria, trypanosomiasis, toxoplasmosis, babesiosis, and filariasis (see Mollison et al. 1987). Acquisition of transmissible spongiform encephalopathies is not considered likely to follow blood transfusion. An epidemiological survey of CJD in the UK revealed that only 16 of 202 cases had a history of blood transfusion and this was not significantly different from controls (Esmonde et al. 1993). However, cases of blood transfusion-acquired CJD have now been reported in England (Llewelyn et al. 2004). Further efforts to exclude infections less common than those already currently screened for in the blood supply must be balanced against the considerable cost of such screening and the impact this might have on blood donation.

Tissue donations have been responsible for the transmission of cytomegalovirus, HIV (L'Age-Stehr et al. 1985), and rabies (Helmick et al. 1987) and may also transmit hepatitis B and hepatitis C. Creutzfeldt–Jakob disease may be acquired during surgical procedures that involve tissue transfer and when this occurs, the incubation period is a matter of months rather than years (Hart 1995). Creutzfeldt–Jakob disease first described by Jakob in 1921, is one of four transmissible spongiform encephalopathies (TSE) found in man. The others being Gerstmann–Straussler–Scheinker syndrome, Kuru (associated with cannibalism in Papua New Guinea), and fatal familial insomnia. TSEs are rare, fatal neurogenerative diseases that cause degeneration of the brain resulting in loss of coordination and faculties. The infectious agents are thought to be unique proteins and are termed 'prions'. Prions replicate by transforming normal cellular prion proteins into abnormal isoform proteins. These abnormal prion proteins, PrP^{res}, then accumulate in the central nervous system causing spongiform changes in gray matter where they trigger neurological symptoms.

Sporadic CJD occurs worldwide. It is rapidly progressive and ultimately results in a fatal disorder of the central nervous system with a long incubation period of 15 months to over 30 years. There are approximately 0.5 to 1 new case per million of the population per year. The similarities between TSEs found in different animal species (e.g. bovine spongiform encephalopathy (BSE)) and those found in man suggest that the disease, in some form or another, may be able to cross the species barrier. Sporadic CJD usually presents in late middle age, mean age 66 years (range, 16–95) with progressive dementia, a duration of illness of <4 months (range, 1–74 months). Diagnosis is based on clinical signs and characteristic waveforms when recording electrical events in the brain (EEG), and as no treatment is available for CJD, medical management remains limited to supportive care.

The new variant of Creutfeldt-Jakob disease (vCJD) was described in the UK in 1996 after the occurrence of ten atypical cases of CJD in patients under 40 years of age, nine of them under 30; median age 28 years (1–74 years). All these patients had common features: young age, a special clinical presentation with psychiatric features at onset, an abnormal duration in the evolution of the disease (14 months on average compared with 2 to 6 months in classical cases of CJD), and a pathognomic neuropathology. Particular neuropathological features were amyloid plaques surrounded by vacuoles (florid plagues) whose distribution in the central nervous system was remarkably similar from one patient to another; a potent PrP immunostaining was identified in the injured areas, and the presence of PrP^{res} was found by Western blot, Moreover, all these patients were homozygous methionine/methionine to codon 129 of the human *PRNP* gene, and did not have a medical history to suggest an iatrogenic or familial origin or disease. In addition, unlike sporadic CJD, no periodical electrophysiological abnormalities were observed; further, the protein 14-3-3, a nonspecific marker usually found positive in sporadic forms of CJD, was not detected. Finally, hyperdense signals to cerebral magnetic resonance imaging (MRI) have been described in the post-hypothalamus area (Pulvinar sign, not seen in sporadic) and can be a helpful diagnostic feature in cases with suggestive clinical picture. This form of CJD was suspected to be the consequence of infection in man with the bovine spongiform encephalopathy (BSE) agent as no other etiological hypothesis could reasonably be considered. The evidence that this is indeed the case is compelling, with BSE manifesting itself as a novel human prion disease – variant Creutzfeldt-Jakob Disease (vCJD), with temporal association with consumption of bovine central nervous system material in food. First exposure was thought to have occurred in 1983, peak exposure 1989, last exposure in 1995. First cases of variant CJD, identified retrospectively, occurred in 1993. Incubation of vCJD is governed by infective dose and methionine/methionine at codon 129. Experimental transmission of BSE and vCJD in bovine transgenic mice have shown similar brain pathology characteristics (possibly satisfying Koch's postulates).

Despite many sensational reports in the media, TSEs although infectious are not easily transmissible as this requires specific material from the affected individual's tissue from or adjacent to their central nervous system. For this reason isolation of sufferers is not necessary. Thorough cleaning and sterilization of surgical instruments is strongly recommended for instruments used on known or suspected CJD cases. Cases of iatrogenic transmission of classical CJD have been reported (corneal grafts, pituitary growth hormone, dura mater grafts). As of 2002 there was no evidence implicating iatrogenic transmission of vCJD (Spencer and Ridgway 2002). This picture has now changed (see above).

INFECTION FROM ACCIDENTAL INOCULATION

In the past, tuberculosis of the skin ('prosector's wart') was a common consequence of inoculation and is once again a potential risk from HIV patients heavily infected with *M. tuberculosis* (Kramer et al. 1993). In the pre-antibiotic era, infection by a needlestick injury with *S. pyogenes* might result in septicemia and death, as observed by Semmelweiss in his colleague, Kolletschka. Such events remain a hazard, though a much reduced one (Hawkey et al. 1980). The main risks of such injuries, however, are infection with hepatitis B and C viruses and HIV.

HEPATITIS B AND C AND HIV INFECTION IN HOSPITALS

Hepatitis B and C viruses and HIV are the pathogens most likely to be transmitted from blood and tissue fluids (Zuckerman 2002). Bodily secretions from infected patients contain much lower concentrations of virus, or none at all. The risk of transmission to staff is greatest for those with the highest exposure to blood and to injuries with sharp instruments, but a history of a definite incident is not always given by hospital staff members who develop hepatitis B. The risk of acquiring hepatitis B from an infectious carrier in an inoculation incident is significant, especially if the patient is e-antigen positive (HBeAg). An investigation following the identification of an HBeAg-positive cardiac surgeon revealed that 13 percent of susceptible patients contracted hepatitis B despite good infection control practice (Harpaz et al. 1996). Until recently it was considered that the risk of nonsocial acquisition from HBeAg-negative staff was low, but a recent report describes spread from HbeAg-negative surgeons with precore mutations. These mutations prevented the expression of HBeAg, but not the assembly of infectious virus and quantitative measurements of HBV DNA may be necessary to fully assess the risk of transmission in surgical and other settings (Incident Investigation Teams and others 1997). Currently, in the UK and Ireland, all healthcare workers performing exposure prone procedures (EPP) are required to be able to demonstrate immunity to hepatitis B. Hepatitis B-infected healthcare workers who are e-antigen negative and who perform EPPs should have their viral loads measured, and those with viral loads exceeding 10^3 genome equivalents per ml should not perform EPPs in future (NHS Executive 2000).

It is clear that the risk of transmission of HIV to staff is very small; of 1 036 subjects included in several series, with adequate epidemiological and serological investigation of percutaneous or mucous-membrane exposure to blood or tissue fluid from known HIV-positive patients, only three (0.3 percent) showed seroconversion (Centers for Disease Control 1987). More recently, only four of 1 103 healthcare workers with percutaneous exposure to HIV-infected blood seroconverted and in one case this occurred following post-exposure zidovudine (Tokars et al. 1993). The risk of a patient acquiring HIV from an infected healthcare worker has been the subject of much debate, some of it ill-informed, but has raised the issue of screening healthcare workers for HIV. A retrospective study of more than 6 400 patients of an infected Florida dentist revealed 28 with HIV infection, of whom 24 had behavioral risk factors. Analysis of the viral gene sequences from the dentist and his patients excluded a possible link with the 24 with behavioral risk factors, but not with the remaining four (Jaffe et al. 1994). A survey of 22 171 patients of 51 infected healthcare workers conducted by the Centers for Disease Control, Atlanta, USA failed to reveal evidence of transmission from healthcare worker to patient (Robert et al. 1995). A cost–benefit analysis of screening surgeons for HIV as a strategy to minimize transmission to patients did not support this approach as cost-effective (Owens et al. 1995). In the UK, recommendations on the investigation of patients who have been cared for by a member of staff who is subsequently identified as HIV-positive, are available (Expert Advisory Group on AIDS and the Advisory Group on Hepatitis 1998).

Post-exposure prophylaxis (PEP) against HIV should be considered if there has been possible exposure to HIV-infected blood or body fluid (Expert Advisory Group on AIDS 2000). The initial risk assessment is based on the potential for viral transmission, i.e. the type of body fluid involved (e.g. blood is high risk), the route (e.g. deep injury by a blood-containing or stained device) or/and severity of exposure (e.g. injury with a needle that has been in the source patient's artery or vein; and/or terminal HIV-related illness in the source patient). Some occupational exposures after careful assessment may not be considered to be significant, that is they do not have potential for HIV transmission, i.e. splashes on to intact skin. In such circumstances PEP is not indicated. If a significant exposure has occurred and the source patient is known to be HIV-positive, PEP should be commenced, the first dose should be given within 1 h of the incident. Based on the results of a HIV test on the donor (with informed consent) the healthcare worker, advised by a specialist clinician can make an informed decision on whether to continue with PEP. However, the exact mechanisms of HIV infection are not fully understood, therefore if more than 1 h has elapsed after exposure this does not automatically preclude starting PEP. It is worth considering starting PEP up to 2 weeks following exposure, however specialist advice should be sought.

Hepatitis C (see Hepatitis C in the *Virology* volume in this series), recognized in the last decade as the major cause of non-A non-B hepatitis following blood transfusion, is encountered worldwide with especially high prevalence in Japan and the southern part of the USA, and may persist in 80 percent of infected patients (van der Poel et al. 1994). Some patient groups have a higher seroprevalence; 3.3 percent

of Dutch hemophilia patients were positive compared with 0.03 percent of blood donors (Schneeberger et al. 1993). Acquisition associated with particular occupations is also described; oral surgeons had a higher incidence (9.3 percent) than dentists (0.97 percent) or unselected blood donors (0.14 percent) in one study (Klein et al. 1991). The risk of seroconversion following a needlestick incident is approximately 3 percent, which is intermediate between HIV (0.3 percent) and hepatitis B (up to 30 percent for hepatitis B eAg positive donors). At present, the risk of a hepatitis C-positive healthcare worker transmitting infection to patients is not certain. An investigation of an incident involving a hepatitis C-positive cardiac surgeon revealed that six of 222 patients followed up contracted postoperative hepatitis; in five patients the viral gene sequences were similar to those of the surgeon (Esteban et al. 1996). Several other reports of hepatitis C transmission from healthcare workers to patients have since occurred (Gunson et al. 2003). The lower risk of transmission of hepatitis C compared with hepatitis B is unfortunately counterbalanced by the greater risk of chronic hepatitis C infection (80 percent), which may in turn lead to cirrhosis or hepatocellular carcinoma. In the UK, healthcare workers entering training to specialities that require practice of exposure prone procedures (EPPs) are now required to be screened for hepatitis C. Healthcare workers that are found to have high levels of hepatitis C RNA in blood are required to cease performing EPPs until RNA levels decline, possibly following interferon/ribivirin treatment. This policy approach is, however, not universal, and in some other countries hepatitis C infected healthcare workers are being allowed to continue to practice after disclosure of their infection status (Barrigar et al. 2001).

Active hepatitis B immunization should be given to those at greatest risk (Mulley et al. 1982) and this and hepatitis B immune globulin (e.g. vaccine staus incomplete/unknown) may be used as post-exposure prophylaxis (Grady et al. 1978). The action needed in the immediate post-exposure period to protect a healthcare worker against hepatitis B is dependent on the vaccination status of the healthcare worker and (where known) the hepatitis B surface antigen status of the source patient. Other measures are clearly to be directed against the risk of inoculation of blood. With the recognition of new agents (e.g. hepatitis C) transmissible by blood and the likelihood of others to follow, control measures have more and more emphasized good practice when handling blood, blood products, and other fluids such as cerebrospinal fluid, irrespective of patient source (Expert Advisory Group on AIDS and the Advisory Group on Hepatitis 1998). These are referred to as universal precautions and include greater awareness of the risks by staff, staff covering cuts or abrasions, careful disposal of sharps and clinical waste, and the use of gloves and gowns when in contact with body fluids (Board of Science and Education 1996; Expert Advisory Group on AIDS and the Advisory Group on Hepatitis 1998). Additional precautions may be taken with known infected patients, or those suspected of being infected (e.g. intravenous drug abusers), but the adoption of universal precautions at all times minimizes the risks to staff and patients when a patient is not known or considered to be in an at-risk group. Guidelines issued in the UK to minimize acquisition of hepatitis B and HIV during surgery, which would also largely apply to hepatitis C, emphasize good practice at all times, e.g. avoidance of passing sharps by hand, with additional precautions such as double gloving when operating on positive patients or those in at-risk groups (Joint Working Party of the Hospital Infection Society and the Surgical Infection Study Group 1992). Continuing education on basic techniques to avoid inoculation risk incidents is important; taking sharps boxes for the disposal of needles to the patient's bedside reduced the number of recapped needles (a practice likely to place the healthcare worker at risk of a needlestick incident) from 33 to 18 percent (Makofsky and Cone 1993).

Testing for hepatitis B surface antigen (HBsAg) has been used to define more closely the patients who present an 'inoculation risk' and identification of HBeAg and antibody (HBeAb) to define the degree of infectivity. Screening of patients for hepatitis C is not usually indicated as an infection control measure. Testing for HIV with consent is not recommended at present, partly because of the implications of detecting seropositivity in a symptomless patient and partly because of the lack of a sufficiently sensitive and specific antigen test to identify infected patients before antibody appears. Testing for hepatitis B, hepatitis C, and HIV is essential before tissue donation and recommended in certain other defined situations.

Containment measures for identified patients should concentrate on the risks associated with invasive procedures and bleeding, and especially with surgical operations and obstetric deliveries. Single-room isolation is required only for certain patients, e.g. those with mental disturbance, uncontrolled bleeding, or dual infection with HIV and another disease, such as tuberculosis. In deciding whether a patient requires single-room isolation, consideration should also be given to the psychological effects this may have. The standard decontamination measures for crockery, bedpans, etc., are adequate. For invasive procedures, limiting the number of staff present, providing adequate protective clothing, including precautions against splash on mucous membranes, limiting and containing blood loss as far as possible, care with sharp instruments, and adequate decontamination of instruments are the principles to apply. Detailed recommendations for the care of HBsAg or HIV risk patients have been formulated (Expert Advisory Group on AIDS and the Advisory Group on Hepatitis 1998; Expert Advisory Group on AIDS 2000).

INFECTION FROM CONTAMINATED BLOOD

Extrinsic contamination of donor blood with small numbers of bacteria is not uncommon and serious consequences of this are rare. Occasionally, stored blood may contain large numbers of bacteria (Braude et al. 1955), often psychrotrophs, and septicemia and shock may occur in the recipient (McEntegart 1956). The range of possible organisms and the risks associated with erythrocytes, whole blood, and platelets together with advice on how to investigate outbreaks and prevent such occurrences have been well reviewed (Wagner et al. 1994).

INFECTION FROM CONTAMINATED INFUSION FLUIDS

Major outbreaks of serious infection and endotoxic shock have been caused by heavily colonized infusion fluids other than blood. Some accidents were due to failure of sterilization during commercial manufacture (Meers et al. 1973), and others to the introduction of microorganisms from cooling water in sterilizers (Phillips et al. 1972) or from contaminated closures which release their bacteria into the infusion fluid during manipulation in the ward. Infusion fluid in reservoirs or administration sets can become colonized during use, from cracks in containers or during manipulations and additions (Duma et al. 1971). Indeed, a significant proportion of containers becomes contaminated with small numbers of bacteria (Maki et al. 1973). Fluids for total parenteral nutrition, such as protein hydrolysate with or without dextrose, readily support the growth of microorganisms, particularly of *Klebsiella* and *Enterobacter* spp., and of *Candida* spp. Disseminated fungal infection has been particularly associated with total parenteral nutrition, but not all episodes have resulted from contamination of fluid in the reservoir or administration set (Goldmann and Maki 1973). The risk can be reduced by care with all manipulations or by having all additions to intravenous fluids made by skilled staff working in controlled environmental conditions. Containers and administration sets should be changed every 48 h; more frequent changing is unnecessary (Buxton et al. 1979). The use of bacterial filters, i.e. in administration sets, has done little to reduce infection (Collin et al. 1973). This may indicate that infection related to the intravascular cannula is more common than colonization of fluid in the rest of the system.

HOSPITAL INFECTIONS AT VARIOUS BODY SITES

Surgical wounds and other soft tissue sites

Surgical site infections (SSI) are important numerically and as a cause of morbidity and prolonged hospital stay. In a prevalence survey (Emmerson et al. 1996) it accounted for 12.3 percent of hospital-acquired infections. In the USA incidence study, SSI accounted for 24 percent of nosocomial infection. In some surveys the definition of SSI was based on a simple, easily observed character such as the presence of pus in the wound and this has the advantages of minimizing observer variability. A more complex definition, making use of several other signs of inflammation (e.g. erythema), can be used with an elaborate scoring system (A.P. Wilson 1995). This may increase the likelihood that significant differences will be observed in comparative trials. The definition should be based on clinical observation. It may be useful to culture all infected wounds for microbiological surveillance purposes, but the presence of pathogenic bacteria in itself does not imply infection. The recorded incidence of infection will also depend on the length of postoperative stay and the degree of follow-up after discharge from hospital (Bailey et al. 1992; Weigelt et al. 1992; Byrne et al. 1994; Emmerson 1995).

Several investigations have been made, in sufficiently large numbers of patients, of the factors predisposing to SSI, to determine where improvements in practice should be directed (e.g. Cruse and Foord 1973). Regression analysis has been employed to separate variables. Surgical procedures may be crudely divided as follows: ‘clean’, when no inflammation is encountered and no colonized body system is entered; ‘clean contaminated’, when a colonized system, e.g. gastrointestinal or respiratory, is entered, but there is no significant spillage; ‘contaminated’, when inflammation, but not pus, is encountered or spillage from a viscus occurs; and ‘dirty’, when a perforated viscus or pus is encountered. The incidence of infection should be less than 5 percent for clean operations; some surgical teams may record a rate of less than 1 percent (Cruse and Foord 1973). On the other hand, operations on the left colon or rectum may be followed by wound infection in more than 30 percent of patients if antibiotic prophylaxis is not given. Refinements of this classification system have been suggested. It may be more useful to consider individual types of operation separately. For example, Cesarean section, though included in ‘clean’ surgery, may have a high infection rate (Beattie et al. 1994; Henderson and Love 1995).
